On color confinement

Adriano Di Giacomo
Pisa University and INFN Sezione di Pisa, ITALY

The status of the theory of color confinement is discussed.

1. Introduction

Quarks and gluons are the constituents of hadrons and the fundamental fields of the QCD Lagrangean.

\[ L_{QCD} = -\frac{1}{4} \text{Tr}[G_{\mu\nu}G^{\mu\nu}] + \Sigma_f \bar{\psi}(iD - m_f)\psi \]  
(1)

Quarks can be detected by use of electroweak probes at short distances. They have never been observed as free particles. The experimental upper limits to the existence of free quarks can be found in Particle Data Group reports [1].

The upper limit to the ratio of the quark abundance in nature \( n_q \) to that of the nucleons \( n_n \) is \( \frac{n_q}{n_n} < 10^{-27} \) to be compared with the expected value in the Standard Cosmological Model \( 10^{-12} \).

The inclusive cross section \( \sigma_p \) to produce a quark or an antiquark has upper limit \( 10^{-40} \text{cm}^2 \) to be compared with the value expected in the absence of confinement \( 10^{-25} \text{cm}^2 \).

A suppression factor of \( 10^{-15} \) can only have as a natural explanation that \( n_q = 0 \) and \( \sigma_q = 0 \) due to some symmetry.

This phenomenon is called color confinement: asymptotic particle in QCD are only colorless.

The obvious question is then: does QCD imply color confinement, and, if so, by what mechanism? What is the symmetry which produces confinement?

For the first time it was conjectured in ref[2] that the Hagedorn limiting temperature \( T_h \) could in fact correspond to a deconfining phase transition from hadrons to a gas of quarks and gluons (the so called Quark Gluon Plasma).

Experiments colliding heavy ions have been set up at CERN and at Brookhaven to detect such transition. It is not clear what would be the smoking-gun signal for that transition and no clear statement can be done up to now.

Virtual experiments, i.e. numerical simulations of the theory on the lattice have instead demonstrated the existence of a deconfining transition. Lattice Montecarlo techniques produce a discretized approximant to the functional Feynman integral which defines QCD. If the lattice spacing \( a \) is small compared to hadronic scale \( \lambda \) and \( \lambda \) is in turn much smaller than the lattice size \( L \) the numerical estimate can be a good approximation to the functional integral.

Also QCD at finite temperature can be simulated by similar techniques. The partition function \( Tr[e^{-\frac{L}{T}A} = \int [dA_{\mu}] [d\bar{\psi}] [d\psi] e^{\int dt A_{\mu}(t, x)} (1) \)

On lattice

\[ T = \frac{1}{a N_t} \]  
(3)

with \( a = a(\beta, m) \) the lattice spacing, \( \beta = \frac{2N}{g^2} \) the usual lattice variable. The integral in Eq(1) is computed by simulating on a lattice with time extension \( L_t \) and space extension \( L_s \) with \( L_s \gg L_t \).

Renormalization group arguments give

\[ a \propto \frac{1}{\Lambda_L L} \alpha_0 \]  
(4)

with

\[ b_0 = -\frac{1}{(4\pi)^2} \left[ \frac{11}{3} N - \frac{2}{3} N_f \right] \]  
(5)

the (negative) coefficient of the lowest order term of the \( \beta \) function.

The negative sign means asymptotic freedom. \( \Lambda_L \) is the physical scale of the lattice regularized QCD.

\( T \) is given by Eq(3)

\[ T = \frac{\Lambda_L e^{-b \alpha}}{L_t} \]  
(6)

High \( T \) corresponds to small \( g^2 \) (order), low \( T \) to large \( g^2 \) (disorder), the opposite of what usually happens to ordinary systems in statistical mechanics.

This peculiar fact naturally brings us to Duality [4, 5].

2. Duality

Duality is a deep concept in statistical mechanics and field theory. It applies to systems in \( (d + 1) \) dimensions which can have topologically non trivial excitations in \( d \) dimensions.

These systems admit two complementary descriptions.
1) A direct description in terms of local fields $\Phi(x)$, with $\langle \Phi \rangle$ the order parameters, in which the topological excitations $\mu$ are non local. This description is convenient in the weak coupling regime $g < 1$

2) A dual description in which the topological excitations $\mu$ are local fields and $\langle \mu \rangle$ the (dis)order parameters. In this description the original $\Phi$ fields are non local. The dual coupling being $gD \approx \frac{1}{g}$ this description is convenient at large $g$ (strong coupling). Duality maps the strong coupling regime of the direct description into the weak coupling of the dual and vice versa.

The prototype system for duality is the 2d Ising model in which the field is a dicotomic variable $\sigma = \pm 1$ defined on the sites of a square lattice. The Lagrangean is the sum on nearest neighbors of a ferromagnetic coupling $S = -\Sigma_{ij} \bar{x}_{ij} \sigma_i \sigma_j$. Putting $g = \frac{T}{J}$ the partition function is $Z[g, \sigma] = \Sigma e^S$.

Identifying one of the coordinate axes, $x$, with space, the other one $t$ with time the topological excitations $\mu$ are kinks and anti-kinks: a kink $\mu(x, t)$ is a spatial configuration at time $t$ with $\sigma = -1$ at he sites $x < \bar{x}$, $x = +1$ at $x \geq \bar{x}$, an anti-kink has opposite signs. It is easily shown that also the operator $\mu$ which creates a kink has eigenvalues $\pm 1$.

Duality for this model is the equality $\bar{Z}$

$$Z[\beta, \sigma] = Z[\beta', \mu]$$  \hspace{1cm} (7)

where $\beta'$ is defined by the equation

$$\sinh(2\beta') = \frac{1}{\sinh(2\beta)}$$  \hspace{1cm} (8)

Eq’s(7) and(8) summarize what we have said about duality.

Since in QCD the low temperature phase is disordered, it is natural to look for dual variables $\mu$ and for their symmetry, which should be responsible for confinement.

A model example is $N = 2$ SUSY QCD $\bar{3}$ in which dual excitations are known to be monopoles.

Also in ordinary QCD monopoles could be the dual excitations $\bar{3}$ $\bar{8}$, and dual superconductivity of the vacuum the mechanism of confinement.

Here the word dual means that the role of electric and magnetic fields are exchanged with respect to ordinary superconductors: monopoles instead of electric charges condense and Meissner effect acts on electric field instead of magnetic.

The pictorial idea is that the chromoelectric field acting between a $q\bar{q}$ pair is channeled into an Abrikosov flux tube by dual Meissner effect so that the energy is proportional to the distance, which means confinement.

In this mechanism the deconfining phase transition is an order-disorder transition from a state with $\langle \mu \rangle = 0$ to a state with $\langle \mu \rangle = 0$, i.e. from superconducting to normal.

3. Lattice QCD

The only practical known way to study the large distance behavior of QCD, which is related to confinement, is to simulate numerically the theory on a lattice $\bar{8}$.

The first question is how to detect confinement and deconfinement on the lattice. The question is non trivial and parallels the same question in experiments. In the absence of quarks (the so called quenched theory), i.e. in pure gauge theory this question has a clear answer. In the presence of quarks this is not the case any more.

In quenched theory an order parameter can be defined $\bar{9}$ which is the vacuum expectation value of the parallel transport along the time direction across the lattice, the Polyakov line $L(\bar{x})$, which is gauge invariant because of periodic boundary conditions.

$$L(\bar{x}) = Tr[Pe^{\int_0^\beta A_0(\bar{x}, t) dt}]$$  \hspace{1cm} (9)

It can be proved that $\langle L \rangle = e^{- <\mu>}$ with $\mu_q$ the chemical potential of a quark. In the confined phase $\mu_q$ is infinite and $\langle L \rangle = 0$. This can be seen alternatively as follows.

Let $D(x) \equiv \langle L(x) L(\bar{0}) \rangle$ be the Polyakov loop correlator. At large distances by cluster property

$$D(x) \approx_{x \rightarrow \infty} C e^{- \frac{\beta}{2} x^2} + |\langle L \rangle|^2$$  \hspace{1cm} (10)

On the other hand one has for the potential $V(x)$

$$V(x) = -T \ln D(x)$$  \hspace{1cm} (11)

Together with Eq(10) this gives

$$V(x) \approx_{x \rightarrow \infty} \sigma x$$  \hspace{1cm} (12)

if $\langle L \rangle = 0$ and

$$V(x) \approx_{x \rightarrow \infty} const$$  \hspace{1cm} (13)

if $\langle L \rangle \neq 0$.

$\langle L \rangle$ is an order parameter for confinement, the center of the group $Z_3$ is the corresponding symmetry.

A standard finite size scaling analysis of its susceptibility $\chi = \int d^3 x D(x)$ allows to establish that the transition is weak first order $\bar{11}$. The transition temperature it $T \approx 270 Mev$.

An alternative order parameter is the vacuum expectation value of an operator $\mu$ which creates a monopole $\bar{12} \bar{13} \bar{14} \bar{10}$. If the mechanism of dual superconductivity is at work, $\langle \mu \rangle \neq 0$ means dual superconductivity, $\langle \mu \rangle = 0$ normal vacuum.

If dual superconductivity is the correct mechanism of confinement the behavior of this order parameter should coincide with that of the Polyakov line.

In that case one expects $\langle \mu \rangle \neq 0$ for $T < T_c$, $\langle \mu \rangle = 0$ for $T > T_c$. $\langle \mu \rangle$ is the ratio of two partition functions with the same Boltzman factor $\beta = \frac{2\pi}{g}$ $\bar{17}$.

IPM-LHP06-20May
To detect the phase transition one must go to infinite volume. The dependence on the volume $L^3_s$ of susceptibilities is determined by the critical indexes, which in turn identify the order of the transition and its universality class.

Instead of the order parameter $\langle \mu \rangle$ itself it proves convenient to use the related susceptibility
$$\rho \equiv \frac{1}{2\pi^2} n(\nu) .$$

One has, due to the boundary value $\langle \mu \rangle = 1$ at $\beta = 0$
$$\langle \mu \rangle = \epsilon \int_0^\beta d\beta \rho(\beta) \quad (14)$$

For $T > T_c$ we find
$$\rho \approx -|c|L_s + c' \quad (15)$$

which by use of Eq(14) means in the infinite volume limit $\langle \mu \rangle \to 0$ (normal vacuum).

For $T < T_c$, $\rho \to$ finite limit as $L_s \to \infty$, which, again by use of Eq(14) implies $\langle \mu \rangle \neq 0$ (dual superconducting vacuum).

For $T \approx T_c$ we expect scaling, since the correlation length goes large compared to lattice spacing.

Dimensional analysis gives
$$\langle \mu \rangle \approx L_s^\gamma f \left( \frac{a}{\lambda L_s^\tau} \right) \quad (16)$$

with $\gamma$ a possible anomalous dimension, and $\lambda$ the correlation length of the order parameter. Approaching $T_c$, when $\tau \equiv (1 - \frac{1}{T^2}) \to 0$, $\lambda$ diverges as
$$\lambda \propto \tau^{-\nu} \quad (17)$$

so that $\frac{a}{\lambda L_s^\tau} \approx 0$ can be neglected. The variable $\frac{1}{\lambda L_s^\tau}$ can be traded with $\tau L_s^\frac{1}{\nu}$ by use of Eq.(17) so that
$$\langle \mu \rangle \approx L_s^\gamma g(0, \tau L_s^\frac{1}{\nu}) \quad (18)$$
or
$$\rho \approx L_s^\gamma F(\tau L_s^\frac{1}{\nu}) \quad (19)$$

A best fit to the data gives for gauge group $SU(3)$ $\nu = \frac{1}{3}$ which corresponds to first order transition, in agreement with the analysis done with the Polyakov line quoted above. This indicates that dual superconductivity can be the mechanism of color confinement.

Including dynamical quarks explicitly breaks $Z_3$ symmetry and the Polyakov line is not an order parameter any more.

Moreover there is the phenomenon known as string breaking: instead of increasing the potential energy when pulling apart a static $q - \bar{q}$ pair the system prefers to create pairs in the form of pions, so that there is no string tension but there can be confinement.

The situation is depicted schematically in Fig.1 for two quark flavors of equal mass $m$. At large values of the mass quarks decouple and the theory goes to quenched . There the phase transition is first order and well understood.

At $m = 0$ there is a chiral phase transition where the spontaneously broken chiral symmetry is restored : $\langle \bar{\psi} \psi \rangle$ is the order parameter. However at zero values of $m$ chiral symmetry is explicitly broken.

The transition line in the figure is defined by the maxima of a number of susceptibilities (the specific heat $C_V$, the susceptibility of the Polyakov line, the susceptibility of the chiral order parameter $\langle \bar{\psi} \psi \rangle$) which all coincide within statistical errors.

The region above the line is conventionally called "deconfined" , the region below it "confined".

The transition can be explored by use of the dual superconductivity order parameter $\langle \mu \rangle$ [18] and the result is that indeed vacuum is a dual superconductor in the region below the transition line , and goes to normal above it. Moreover the transition is consistent with first order at least in the region of low masses.

The order of the transition across the critical line in Fig (1) is a fundamental issue in the study of confinement. As noticed in Sect.1 a natural explanation of observations on the existence of free quarks is that the deconfining phase transition is an order-disorder transition : a continuous transition (crossover) would imply continuity, and hence would require an unnatural way of explaining the inhibition factors of order $\approx 10^{-15}$ which are observed in nature.

An analysis of the chiral transition based on renormalization group and $4 - \epsilon$ can be made [19], assuming that the relevant critical degrees of freedom are the scalars and pseudoscalars.

The result is that the chiral transition is first order for $N_f \geq 3$.

For $N_f = 2$ two possibilities exist depending on the behavior of axial $U_A(1)$ symmetry across the critical point . That symmetry is broken by anomaly at $T = 0$ and is expected to be restored at some temperature.

If $m_N$ the mass of the singlet pseudoscalar vanishes at $T_c$ then the chiral transition is first order and the

![Figure 1: The phase diagram of $N_f = 2QCD$. The transition line is defined by the maxima of the specific heat and of the susceptibility of the chiral order parameter. $m$ is the quark mass, $\mu$ the baryon chemical potential.](image-url)
same is at $m \neq 0$ in a neighbor of the chiral point $m = 0$.

If instead $m_{\tilde{\eta}} = 0$ at $T_c$ the chiral transition is second order in the universality class of $O(4)$ and a crossover at $m \neq 0$. In this case a tricritical point exists at non zero value of the baryon chemical potential [See. Fig.(1)] which could be observed in heavy ion experiments, but has not been observed up to now.

The order of the chiral transition can be investigated on the lattice by looking at the behavior of the specific heat and of other susceptibilities as a function of the spatial volume.

This analysis requires large amounts of computer time on supercomputers. Pioneering work on the subject was inconclusive. More recently a big effort has been put on the problem\cite{20} which is still going on.

The motivation for such an effort is the relevance of this issue to the understanding of confinement mechanisms. All the existing evidence points to a first order transition, or to an order disorder nature of the deconfining transition. This also agrees with the observed behavior of the order parameter $\mu$ for dual superconductivity \cite{15}. More work is needed, however, to fully clarify the situation.
