## 1 Introduction

The high luminosity delivered by LEP after the doubling of the  $e^+e^-$  collision energy means that LEP2 is now providing substantial samples of W bosons with which to make complementary tests of the Standard Model to those of LEP1. This, together with collision energies in excess of 200 GeV, is ensuring that the three central physics goals of the LEP2 program are properly explored: the precise measurement of the W mass; the measurement of vector-boson self-interactions; and the search for new particles. This review discusses the first two of these objectives: the third is addressed elsewhere in these proceedings [1].

After a hesitant start of LEP above the W pair production threshold in 1996, subsequent years have seen increasingly large data samples accumulated by the experiments (Table 1). A total of around  $480 \text{ pb}^{-1}$  has now been recorded by each experiment at LEP2. This integrated exposure can be expected to pass  $650 \text{ pb}^{-1}$  by the time data-taking is completed in the second half of 2000. During 1999, the collision energy has reached, and surpassed<sup>1</sup>, its design value of  $\sqrt{s} = 200 \text{ GeV}$ . As illustrated in Fig. 1, the machine performance has been better than ever in 1999, in spite of the increased load on the RF system imposed by the higher energies.

This report describes various Standard Model tests made with the first parts of the LEP2 data. Because analyses are in varying stages of completion, essentially all results quoted are preliminary. In addition to the measurements made with W pairs, studies of fermion-pair production, QED tests, and Z pair production are reviewed.

---

<sup>1</sup>At the time of the conference, the LEP collision energy had just reached 200 GeV. The figures quoted in the text refer to the achievements at the time of writing (November 1999).

Center-of-mass energy (GeV)	161	172	183	189	192	196	200	202
Integ. luminosity ( $\text{pb}^{-1}$ )	10	10	55	180	30	80	80	40
Collection year	1996	1997	1998		—	1999	—	

Table 1: Accumulated data samples at LEP2. Integrated luminosity totals are quoted per experiment, and are approximate.

Figure 1: Integrated luminosity delivered per experiment, in the later years of LEP1 and so far during LEP2.

## 2 Fermion-pair production

Although two to three orders of magnitudes less than at LEP1 (Fig. 2b), the cross-section for fermion-pair production at LEP2 is still high compared to many other processes. The presence of the Z resonance at lower center-of-mass energies strongly affects the characteristics of events at higher energies, because initial-state photon radiation leads to so-called “radiative return” events where the fermion-pair system has an invariant mass ( $\sqrt{s'}$ ) close to the Z. As a result, two typical populations of fermion-pair events are observed, as illustrated in Fig. 2a: the radiative return events with  $\sqrt{s'} \approx m_Z$ , and non-radiative events with  $\sqrt{s'} \approx \sqrt{s}$ . The latter events are of more interest, as they probe the full center-of-

mass energy scale.

Figure 2: a) Typical reconstructed  $\sqrt{s'}/\sqrt{s}$  distribution [3]; b) Measured cross-sections for hadronic events from  $q\bar{q}$  production [4].

Figure 3: a) Typical reconstructed  $\cos \theta_{\mu^-}$  distribution [5]; b) Measured asymmetries for muon and tau pair production [2].

The cross-sections for fermion-pair production have been measured [2, 3, 4, 5] in the hadronic channel ( $q\bar{q}$  production), and for  $\mu^+\mu^-$ ,  $\tau^+\tau^-$  and  $e^+e^-$  (the latter dominated by t-channel Bhabha scattering). The Standard Model expectation describes the data well, as shown in Fig. 4a for the combined LEP cross-sections.

Figure 4: a) LEP average fermion-pair cross-sections [6] scaled by the Standard Model expectation, from ZFITTER [7]; b) LEP average forward-backward asymmetries, compared with the ZFITTER prediction.

For muon and tau pair production, the easily identifiable lepton charge is further employed to measure the forward-backward asymmetry of the non-radiative events. As shown in Fig. 3, the asymmetry for non-radiative events is large at these energies, in contrast to that at LEP1. Again, the Standard Model expectation describes the data well. An expanded view of the higher energy LEP-averaged asymmetries is shown in Fig. 4b.

In addition to the results presented, measurements have further been made of heavy quark pair production at LEP2 energies [2, 8]. They too are well described by the Standard Model expectation. Constraints on a wide range of new physics scenarios have been placed with the fermion-pair data, ranging from four-fermion contact interactions to electroweak scale quantum gravity [1, 2, 3, 5, 9]. Discussion of these topics is beyond the scope of this report.

### 3 QED tests

A few electroweak processes at LEP2 do not have any significant contribution from massive vector boson exchange, and so may be employed to test the adequacy of quantum electrodynamics, QED, at the highest LEP energies.

Tests have been made with the process  $e^+e^- \rightarrow \gamma\gamma(\gamma)$  [10]. Possible deviations from the QED expectation are parameterized in terms of an effective cut-off parameter  $\Lambda_{\pm}$  [11]. Typical limits obtained by each experiment are  $\Lambda_{\pm} \geq 290$  GeV

at 95% CL.

## 4 W pair production and decays

Figure 5: The three W pair production diagrams. The fermions from W decay are also shown.

At LEP2, three diagrams contribute to doubly-resonant W pair production, as shown in Fig. 5. The neutrino exchange diagram dominates close to the W pair threshold, and in the Standard Model the main effect of the other two diagrams at LEP energies is a negative interference. This is illustrated in Fig. 6, where the expected cross-section is shown with the full Standard Model structure, and if one or both of the diagrams with triple vector boson couplings is omitted. The effect of the triple gauge coupling is discussed further in Section 6.

Decay mode	Efficiency	Purity
$WW \rightarrow q\bar{q}q\bar{q}$	90%	80%
$WW \rightarrow q\bar{q}\ell\nu$	82%	90%
$WW \rightarrow \ell\nu\ell\nu$	60-80%	90%

Table 2: Typical W pair event selection efficiencies and purities.

The typical selection efficiencies and purities for W pair events [12] are given in Table 2. The main backgrounds arise from other four-fermion processes, and non-radiative  $q\bar{q}$  events in the  $q\bar{q}q\bar{q}$  and  $q\bar{q}\ell\nu$  decay channels, or lepton-pair production and multiperipheral interactions in the  $\ell\nu\ell\nu$  channel. The cross-sections measured [12, 6] are shown in Fig. 6 for the various LEP2 center-of-mass

Figure 6: LEP average W pair production cross-section [12, 6], corrected to correspond to the three doubly-resonant W pair production diagrams (CC03). The predicted cross-sections are from GENTLE [13].

energies. The peak cross-section, of around 17 pb, is more than three orders of magnitude less than the Z cross-section at LEP1: consequently, even with the high luminosities collected at LEP2, the W pair events number a few thousand per experiment. Nonetheless, precision electroweak measurements can be made.

Decay mode	Branching ratio (%)
$W \rightarrow e\nu$	$10.61 \pm 0.25$
$W \rightarrow \mu\nu$	$10.65 \pm 0.24$
$W \rightarrow \tau\nu$	$10.82 \pm 0.32$
$W \rightarrow \ell\nu$	$10.68 \pm 0.13$
$W \rightarrow q\bar{q}$	$67.96 \pm 0.41$

Table 3: LEP average W decay branching ratio measurements [12, 6]. Results are preliminary.

The branching ratio for W decays via the electron, muon, tau, and hadronic modes have been measured by all four experiments [12]. The LEP average results are given in Table 3. The results for the individual leptonic channels are con-

sistent with lepton universality, and the average leptonic branching ratio is also consistent with the Standard Model expectation. The precision of the measurement of  $B(W \rightarrow \ell\nu)$  from LEP is now better than that from  $p\bar{p}$  colliders.

The leptonic  $W$  branching ratio can be re-interpreted [12] in terms of the CKM matrix element  $V_{CS}$  without need for a CKM unitarity constraint, using the relatively well-known values of other CKM matrix elements involving light quarks [14]. These indirect constraints currently lead to a value [6] of  $|V_{CS}| = 0.997 \pm 0.020$ , much more precise than the value derived from  $D$  decays of  $1.04 \pm 0.16$  [14].

## 5 Measurement of the $W$ mass and width

Figure 7: Reconstructed  $W$  mass distributions obtained from the kinematic fits, for the four-quark and three  $q\bar{q}\ell\nu$   $WW$  decay channels [15, 16].

At center-of-mass energies above the  $W$  pair threshold, the technique for measuring the  $W$  mass lies in the reconstruction of the directions and energies of the

four primary  $W$  decay products. These may be either four quarks, approximated by four jet directions and energies, for the  $q\bar{q}q\bar{q}$  channel; or two quarks/jets and a charged lepton for the  $q\bar{q}\ell\nu$  channel, deducing the neutrino direction and energy from the missing momentum in the event. Decays to  $\ell\nu\ell\nu$  are of limited use because at least two neutrinos are undetected. The  $W$  decay products are paired up to give reconstructed  $W$  mass estimates. A substantial improvement is made in the mass resolution for both  $q\bar{q}q\bar{q}$  and  $q\bar{q}\ell\nu$  channels by applying a kinematic fit, constraining the total energy and momentum in the event to be that of the known colliding electron-positron system, making a small correction for possible unobserved initial-state radiation.

Typical reconstructed mass distributions from the kinematic fit are shown in Fig. 7, for the  $q\bar{q}q\bar{q}$  and three  $q\bar{q}\ell\nu$  channels. Clear  $W$  mass peaks are observed, in some cases with very low backgrounds. The  $W$  mass is extracted [15, 16] from the measured  $W$  masses in each data event using a Monte Carlo technique, the details of which differ from one experiment to another. The Monte Carlo techniques have in common that they use full detector simulations to correct for the effects of finite detector acceptance and resolution, as well as initial-state radiation, and in most cases a reweighting technique is used to model different true  $W$  mass values. The results obtained from the fits are given in Table 4, separately for the  $q\bar{q}q\bar{q}$  and  $q\bar{q}\ell\nu$  channels (in the case of ALEPH, an analysis employing also purely leptonic  $W$  decays is included). For all of these fits, the  $W$  width is taken to have its expected Standard Model dependence on the  $W$  mass. The results are consistent with each other, and also with the  $W$  mass extracted from the measurement of the  $W$  pair threshold cross-section at 161 GeV. The overall LEP average  $W$  mass measurement obtained is thus [6]:

$$m_W = 80.350 \pm 0.056 \text{ GeV} \quad (\text{LEP}) . \quad (1)$$

Experiment	Mass measurement (GeV)	
	$WW \rightarrow q\bar{q}q\bar{q}$	$WW \rightarrow q\bar{q}\ell\nu(\ell\nu\ell\nu)$
ALEPH	$80.561 \pm 0.121$	$80.343 \pm 0.098$
DELPHI	$80.367 \pm 0.115$	$80.297 \pm 0.155$
L3	$80.656 \pm 0.156$	$80.224 \pm 0.135$
OPAL	$80.345 \pm 0.134$	$80.656 \pm 0.156$
LEP	$80.429 \pm 0.089$	$80.313 \pm 0.063$
LEP (161 GeV)	$80.40 \pm 0.22$	
Combined	$80.350 \pm 0.056$	

Table 4: LEP  $W$  mass results from the different channels and experiments [15, 16, 6]. All results except those from 161 GeV are preliminary.

The LEP  $W$  mass measurement is slightly more precise than that from  $p\bar{p}$  colliders, of  $80.448 \pm 0.062$  GeV [17]. The two measurements have similar precision, but use very different techniques, and so are essentially uncorrelated. A substantial improvement is obtained by averaging them [6]:

$$m_W = 80.394 \pm 0.042 \text{ GeV (World Average) .} \quad (2)$$

The width of the  $W$  mass distributions shown in Fig. 7 has components from the true  $W$  width and from detector resolution. In many events, the mass resolution is comparable to, or better than, the true width. It is consequently possible to measure directly both the  $W$  mass and width, and in practice the two results are little correlated. This has been done by three experiments [16], the combined result currently being:

$$\Gamma_W = 2.12 \pm 0.20 \text{ GeV.} \quad (3)$$

With the full LEP2 statistics, the precision should improve on the current measurement from CDF, of  $2.055 \pm 0.125$  GeV [17].

With the current uncertainties, the measurement of the  $W$  mass starts to provide an interesting further test of the Standard Model relative to other precision electroweak measurements. This is illustrated in Fig. 8 [6]: the predicted  $W$  and top masses extracted from fits to lower energy electroweak data are consistent with the direct measurements from LEP and the Tevatron [17], and the precision of the measurements is similar to that of the prediction. From the overlaid curves showing the Standard Model expectation as a function of the Higgs boson mass, it is further evident that both the precise lower energy measurements, and the direct  $W$  and top mass measurements taken together, separately favor a Standard Model Higgs boson in the relatively low mass region.

At the time of writing, the LEP  $W$  mass analyses are in a stage of detailed review and improvement, as careful systematic studies are needed to match the statistical precision: for this reason the  $W$  mass results of all experiments are preliminary. It is not possible to predict with certainty the final  $W$  mass error from LEP2, but it is interesting to consider the main error sources in order to extrapolate to the full data sample. If the present LEP average  $W$  mass result is broken down into statistical and systematic components, they are respectively approximately 36 MeV and 43 MeV. This does not mean simply that a systematic limit is being reached, because the analysis is performed in two channels,  $q\bar{q}q\bar{q}$  and  $q\bar{q}\ell\nu$ , of approximately equal statistical weight, but with different systematic error behavior. In the  $q\bar{q}\ell\nu$  case, the main systematic errors arise from detector calibration uncertainties and Monte Carlo statistics: these are amenable to reduction with more statistics, and are uncorrelated between the different LEP experiments. In neither case do they give a large contribution to the combined LEP error. In the  $q\bar{q}q\bar{q}$  channel, on the other hand, the systematic errors are dominated by

Figure 8: Dashed contour: direct measurements of  $W$  and top masses; Solid contour: predicted values of  $m_W$  and  $m_t$  from LEP1, SLD and neutrino-nucleon scattering precise electroweak data [6]. The diagonal band indicates the expected Standard Model dependence for different Higgs boson masses.

contributions from final-state interaction effects such as color-reconnection [18] and Bose-Einstein correlations [19], and the modeling of backgrounds and fragmentation uncertainties. These error sources are largely correlated between different experiments, and will be relatively difficult to reduce. Consequently, with the full LEP2 data sample, the  $q\bar{q}\ell\nu$  channel analysis should remain statistics limited, but the  $q\bar{q}q\bar{q}$  channel will probably be limited by systematics at some level below the currently estimated error. A realistic expectation for the overall combined  $W$  mass error from LEP2 then lies in the region of 30 MeV.

## 6 Gauge boson self-interactions

As mentioned in Section 4,  $W$  pair production at LEP2 probes the triple gauge boson vertices  $WW\gamma$  and  $WWZ$ . The form and strength of these vertex couplings is

Figure 9: Reconstructed W (a) production [20] and (b) decay angle distributions [23], compared to the Standard Model expectation and different anomalous coupling hypotheses.

unambiguously predicted by the gauge structure of the Standard Model. Possible new physics beyond the Standard Model may additionally bring in extra effective interactions between three gauge bosons without affecting other sectors, mandating a test of this aspect of the theory.

The general lagrangian for the  $WWV$  ( $V=\gamma$  or  $Z$ ) interaction contains 14 parameters. Constraints of C, P, and CP invariance and  $U(1)_{em}$  gauge invariance reduce these to five parameters, and constraints from low energy measurements reduce these further to three, conventionally taken to be  $\kappa_\gamma$ ,  $g_1^Z$ , and  $\lambda_\gamma$ , respectively 1, 1, and 0 in the Standard Model. The LEP experimental analyses are performed in terms of these three variables, or equivalently deviations from their respective Standard Model values.

The triple gauge couplings affect the characteristics of W pair production in three ways: the total cross-section changes, as shown in Fig. 6, by an amount which increases rapidly with  $\sqrt{s}$ ; the production angular distribution of the W is modified, as shown in Fig. 9a; finally, the helicity mixture of the Ws produced at a given  $\cos\theta$  is affected. This last effect can be measured experimentally by using the W decay as a polarization analyzer. Typical W decay angle distributions under different coupling hypotheses are shown in Fig. 9b.

Values of triple gauge coupling parameters are extracted from the W pair data using the W boson production and decay angles [20, 21, 22, 23]. This typically employs so-called optimal observables [24] constructed from these angles, which has the advantage of not requiring analysis of a five-dimensional differential dis-

tribution. The preliminary results obtained, averaging over all experiments and including also the less sensitive single-W and  $\nu\nu\gamma$  constraints [21, 25], are [6]:

$$\kappa_\gamma = 1.04 \pm 0.08 \quad (4)$$

$$g_1^Z = 0.99 \pm 0.03 \quad (5)$$

$$\lambda_\gamma = -0.04 \pm 0.04 \quad (6)$$

strikingly well described by the Standard Model predictions of unity, unity, and zero, respectively. The results are quoted for the case where only one of the anomalous parameters differs from the Standard Model at a time: fits have also been performed allowing up to three parameters to vary at once: consistent results are obtained.

An alternative perspective on the W-pair production process is provided by analyses which directly measure the relative rates of production of transversely and longitudinally polarized W bosons. A recent analysis along these lines by L3 [26] gives the fraction of longitudinal W polarization as  $(24.4 \pm 4.8 \pm 3)\%$  at 189 GeV. Overall, longitudinal W polarization is established at the five standard deviation level. This contrasts with W production from the  $q\bar{q} \rightarrow W$  process at  $p\bar{p}$  colliders, where the W is transversely polarized.

Recently, a study has been carried out by OPAL [27] of the quartic gauge couplings between  $WW\gamma\gamma$  and  $WWZ\gamma$ . These couplings are non-zero in the Standard Model, but the effect on the data is tiny for the LEP2 sample. However, constraints have been placed on possible large anomalous values of these parameters using  $WW\gamma$  production with photon energies above 10 GeV, and also the  $\nu\bar{\nu}\gamma\gamma$  final-state, where there is sensitivity from the W fusion diagrams. This analysis places the first, albeit weak, direct limits on quartic gauge couplings.

## 7 Z pair production

Since 1997, LEP has been running at center-of-mass energies around and above the Z pair production threshold. Unlike the W case, Z pair production involves no triple gauge coupling diagrams in the Standard Model, but instead simply those with  $t$  and  $u$  channel electron exchange. Production is suppressed by factors of  $(1 - 4 \sin^2 \theta_W)$  at two  $eeZ$  vertices, so that the Z pair cross-section is significantly lower than that for W pairs. The measured cross-section [29, 6] is shown in Fig. 10, compared to the Standard Model prediction. A particular interest of this process is that it forms an irreducible background to potential Higgs boson production if the Higgs mass were around the Z mass, in cases where one Z decays to b quarks. Fig. 10 indicates that ZZ production is well understood.

Figure 10: Observed Z pair production cross-section as a function of center-of-mass energy, compared to the Standard Model prediction from YFSZZ [28].

## 8 Summary

With the excellent performance of the LEP machine at high energy in the last couple of years, electroweak physics at LEP2 now truly merits the epithet “precise”. The core measurements of the LEP2 program, the W mass, and the vector boson self-couplings have been made with precision better, in some cases substantially so, than elsewhere. Tests of the Standard Model with other processes serve to confirm the superb description it provides of the data.

Finalization of the current analyses, and inclusion of the 1999 and 2000 data samples, will provide significant further improvements in precision, although requiring care and attention to the encroaching systematic difficulties. By the time of the next Lepton-Photon meeting, the full fruits of this labor should be harvested.

Much credit is due to the LEP electroweak working group for the preparation of most of the averages and figures presented. The work of this team makes the job of a rapporteur simpler and more enjoyable. For their help during the preparation of this talk, I wish to thank: R. Bailey, R. Clare, J. Ellison, M. Grünewald, R. Hemingway, M. Hildreth, E. Lançon, M. Lancaster, C. Matteuzzi, D. Miller, K. Mönig, D. Plane, A. Straessner, D. Strom, M. Thomson, H. Voss, P. Ward

and P. Wells.

## Discussion

**Howard Haber (UCSC):** Could you comment on the maximum energy achievable at LEP?

**Charlton:** Increasing the energy beyond 200 GeV will be difficult, and it is unclear how the performance will evolve. An absolute maximum is 205-206 GeV, but 202-203 GeV may be more realistic.

**Tom Ferbel (University of Rochester):** You mentioned the observation of longitudinal W polarization at LEP2. There is also dominant longitudinal W production in top quark decay, and this has been reported by the Tevatron experiments.

**Charlton:** Yes, that is correct. The significance observed in that case, however, is at a much lower level than that from LEP.

**Michael Peskin (SLAC):** You quoted a large systematic error for the W mass measurement in  $WW \rightarrow q\bar{q}q\bar{q} - 50-90$  MeV—due to color reconnection and Bose-Einstein effects. Models of color reconnection predict observable manifestations in the final state, and since these are not observed, the constraints should put bounds on these errors. Could you comment on this?

**Charlton:** Some models of color-reconnection effects have been excluded by LEP data; however, others will be hard to test even with the full LEP2 statistics. The errors I quoted also have large Monte Carlo statistical components. A final error on the  $q\bar{q}q\bar{q}$  channel from this source of around 30 MeV may be achievable.
