ABSTRACT

We present 5, 8, and 15 GHz total intensity and polarimetric observations of the radio source PKS 2322–123 taken with the Very Large Array (VLA). This small (11 kpc) source is located at the center of the cooling-core cluster Abell 2597. The inner X-ray structure, the radio morphology, and the steep spectral index ($\alpha = -1.8$) in the lobes, all suggest that the radio emission is confined by the ambient X-ray gas. We detect a small region of polarized flux in the southern lobe and are able to calculate a Faraday rotation measure (RM) of 3620 rad m⁻² over this region. Based on these observations and Chandra X-ray data we suggest that the southern lobe has been deflected from its original southwestern orientation to the south and into our line-of-sight. Using the observed RMs and our calculated electron density profiles, and assuming both a uniform and tangled magnetic field topology, we estimate a lower limit of the line-of-sight cluster magnetic field, $B_{\parallel} = 2.1 \mu\text{G}$.

Key words: galaxies: clusters: individual (A 2597) – intergalactic medium – magnetic fields – polarization – radio continuum: galaxies

1 INTRODUCTION

Strong radio galaxies embedded in galaxy clusters have been used successfully to probe the intracluster medium (ICM). Taylor et al. (1994) defined a sample of 14 clusters found in the flux-limited, all-sky X-ray sample devised by Edge et al. (1992), and determined that clusters with nonzero estimated mass flow rates and embedded radio galaxies with $S_{5000} \geq 100$ mJy commonly display significant rotation measures (RM), often in excess of 800 rad m⁻², with the magnitude of the RM proportional to the estimated cooling flow rate. The observed RMs are thought to be caused by Faraday rotation through a magnetized cluster gas, and detailed studies of these high RM sources suggest that minimum cluster magnetic fields of 5 – 10 μG are common in cooling core clusters (Carilli & Taylor 2002).

A 2597 is one of the last in the sample of 14 clusters to be analyzed. Edge et al. (1992) classified A 2597 as a cooling core cluster, and numerous other observations have confirmed nonzero cooling flow rates. Most notably, the analysis of XMM-Newton and Chandra X-ray data by Morris & Fabian (2004) inferred a mass cooling rate of $\sim 50 M_{\odot}$

yr⁻¹ across the central regions of the cluster. As a cooling core cluster, A 2597 is expected to have high-density ambient gas that disturbs the radio jets of embedded sources (Loken et al. 1993). Chandra observations by McNamara et al. (2001) confirm the complex X-ray gas environment, and the detection of extended broad-line H I absorption toward the embedded radio source PKS 2322–123 by O’Dea et al. (1994) can be attributed to a population of clouds condensing out of the hot gas, though the mass rate is only a small fraction of the inferred cooling flow rates. Very Long Baseline Array (VLBA) observations of PKS 2322–123 made by Taylor et al. (1999) show a symmetric parsec-scale jet structure. These observations along with previous radio images by Sarazin et al. (1995) that reveal a kiloparsec-scale, asymmetric, steep-spectrum jet morphology support the idea that the radio galaxy is confined and distorted in the high pressure cluster environment.

Here we discuss our multi-frequency polarimetric VLA observations of the embedded radio source PKS 2322–123 ($z=0.083$). We use the polarized flux associated with synchrotron radiation from the radio jets to calculate RMs, and then estimate cluster magnetic fields assuming two different field topologies. In § 2 we describe our radio observations, in § 3 we calculate an electron density profile based on X-ray observations, in § 4 we present our results, and in § 5

Table 1. Observational Parameters for PKS 2322–123

Date	Frequency (MHz)	Bandwidth (MHz)	Config.	Duration (hours)
Jul 1991	8415/8465	50	A	0.11
Aug 1991	8415/8465	50	A	0.11
Jul 1994	7815/8165	50	B	0.69
Jul 1994	8515/8885	50	B	0.61
Jul 1994	14785/15185	50	B	1.39
Dec 1996	4985	50	A	1.18

we make magnetic field estimates, suggest a source orientation, and compare our observations with the literature. Throughout this paper we assume $H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M = 0.270$, and $\Omega_{\text{vac}} = 0.730$ so that $1'' = 1.542 \text{ kpc}$ at $z = 0.083$.

2 RADIO OBSERVATIONS AND DATA REDUCTION

Very Large Array observations of the radio source PKS 2322–123 were made at 4.985, 7.815, 8.165, 8.415, 8.465, 8.515, 8.885, 14.785 and 15.185 GHz. The total time on source is 1.18 hours at 5 GHz, 1.52 hours at 8 GHz, and 1.39 hours at 15 GHz. Observations in the 5 GHz band were carried out with the phased VLA. Details regarding these observations are given in Table 1. During the July 1994 observations the source 3C 48 was used as the primary flux density calibrator and 3C 138 was used as an absolute reference for the electric vector polarization angle (EVPA), χ . Phase calibration was derived from the nearby compact source 2345–167 with a time between calibrators of ~ 40 minutes. The source 0420+417 was used to obtain instrumental calibration of polarization leakage terms, and was observed over a wide range of parallactic angle. During the December 1996 observations and the July and August 1991 observations, the source 3C 286 was used both as the primary flux density calibrator and as the EVPA calibrator. Phase calibration was derived from nearby compact sources. No polarized intensity images were used from the 1991 and 1996 observations.

The data were reduced in AIPS (Astronomical Image Processing System) following the standard procedures, and Stokes I , Q and U images were produced using the AIPS task IMAGR. We combined multiple frequencies within each observing band to produce Stokes I images with increased sensitivity and better (u, v) coverage. At 8 GHz, the combined data includes observations with the VLA in both the A and B configurations. Where frequencies have been combined, we assume the resultant frequency to be the average of the included frequencies. The spectral index images were made using combined frequency images with matched resolutions. We define the spectral index, α , as $S_\nu \propto \nu^\alpha$.

The Faraday rotation measure image was created from the four frequencies spread out over the 8 GHz observing band in the July 1994 data set. Data at 5 and 15 GHz were not included in the RM map because no polarized flux was detected at these frequencies. For the four frequencies used in the RM map, polarized intensity, P , images and polarization angle, χ , images were derived from Q and U images. A

power (5 GHz)	$6.08 \times 10^{24} \text{ W Hz}^{-1}$
$\langle \text{RM} \rangle$	3620 rad m^{-2}
σ_{RM}	1080 rad m^{-2}

^aRadial velocity is determined from H I absorption observed toward the nucleus of PKS 2322–123 (Taylor et al. 1999).

pixel by pixel least squares fit of χ versus λ^2 gives the RM value and an RM error estimate. Pixels in the RM map were flagged if they have an error in χ greater than 20° for any of the four frequencies used.

During data reduction we found a 0.73 mJy compact source, most likely a background AGN, located at a right ascension of $23^{\text{h}}25^{\text{m}}20^{\text{s}}.94$ and declination of $-12^{\circ}07'05''.52$ (J2000). In order to reduce the sidelobes from this source, we made a large image of PKS 2322–123 and cleaned the 0.73 mJy source.

3 X-RAY OBSERVATIONS

McNamara et al. (2001) report X-ray observations of the galaxy cluster A 2597 made in July 2000 using the Advanced CCD Imaging Spectrometer detector on Chandra. Here, we present a re-analysis of those data using updated software and calibration products.

The standard level-1 event list produced by the Chandra pipeline processing was reprocessed using the *CIAO* (version 3.0.2) software package, including the latest gain maps and calibration products. Bad pixels were removed and standard grade selections applied. Time-dependent gain corrections were applied using A. Vikhlinin’s *apply_gain* routine. The data were cleaned from periods of anomalously high background using the same author’s *lc_clean* script and the recommended energy ranges and bin sizes for the back-illuminated (S3) detector. The net exposure time was 6.9 ks.

The data have been analysed using the methods described by Allen et al. (2004). In brief, concentric annular spectra, centred on the radio source, were extracted from the cleaned events list. Background spectra were extracted from blank-field background data sets. Separate photon-weighted response matrices and effective area files were constructed for each region using the calibration files appropriate for the time of observation. The data were analysed using an enhanced version of the Cambridge image deprojection code and XSPEC (version 11.3: Arnaud 1996). We have used the MEKAL plasma emission code (Kaastra & Mewe 1993; incorporating the Fe-L calculations of Liedhal, Osterheld &

Figure 1. Deprojected electron density profile of A2597 determined from Chandra observations. The dotted line shows the best-fitting β -model.

Goldstein 1995) and the photoelectric absorption models of Balucinska-Church & McCammon (1992). The ACISABS model was used to account for time-dependent contamination along the instrument light path. Only data in the 0.8 – 7.0 keV energy range were used for the analysis. The spectra for all annuli were modelled simultaneously in order to determine the deprojected X-ray gas temperature profile under the assumption of spherical symmetry. These data were then combined with the observed surface brightness profile to constrain the gas density profile.

We have fitted the electron density (n_e) profile for the central 300 kpc of the cluster using a modified King model (Cavaliere & Fusco-Femiano 1976),

$$n_e(r) = n_0(1 + r^2/r_c^2)^{-3\beta/2}. \quad (1)$$

From this analysis we measure a central density, $n_0 = 7.35 \pm 0.32 \times 10^{-2} \text{ cm}^{-3}$, a core radius, $r_c = 27.7 \pm 1.7 \text{ kpc}$, and a slope parameter, $\beta = 0.585 \pm 0.018$. The model fit, which gives an acceptable reduced χ^2 value of 0.96, is shown as a dotted line in Figure 1. The modified King model does not parameterize the gas density at large radii for the A 2597 cluster. In this paper we only use the results of this model in the central 200 kpc where this parametrization adequately describes the gas density.

4 RESULTS

Figure 2 shows total intensity contour images of PKS 2322–123 at 4985, 8377, and 14985 MHz. In all three frequency bands the source has an asymmetric structure about the core; there is one area of diffuse emission located northeast of the core and another area located directly south of the core. We call these areas northern and southern lobes. Both the northern and southern lobes extend out from the core to a distance of approximately $3.5''$, or 5.4 kpc, giving

Figure 2. From top to bottom, total intensity at 4985, 8377, and 14985 MHz. Solid contours start at $0.35 \text{ mJy beam}^{-1}$ and increase by factors of 2. The peak contour flux is 59.3, 30.2, and $42.5 \text{ mJy beam}^{-1}$ for the 4985, 8377, and 14985 MHz images, respectively. The restoring beam is a Gaussian with FWHM $0.52 \times 0.43 \text{ arcsec}^2$ in P.A. 17° ; $0.39 \times 0.23 \text{ arcsec}^2$ in P.A. -23° ; and $0.62 \times 0.42 \text{ arcsec}^2$ in P.A. -9° . The respective noise in the images is 44, 91, and $86 \mu\text{Jy beam}^{-1}$.

Figure 3. Spectral index map made from 8377 MHz and 14985 MHz. The colorbar ranges from $\alpha_{8377}^{14985} = -3$ to $+1$. Overlaid contours show total intensity at 14985 MHz. Solid contours start at $0.4 \text{ mJy beam}^{-1}$ and increase by factors of 2. Dashed contours represent $-0.4 \text{ mJy beam}^{-1}$. The peak contour flux is $43.1 \text{ mJy beam}^{-1}$. The restoring beam is a circular Gaussian with a FWHM of $0.5''$. The overlaid symbols (square, diamond, triangle, and cross) mark the locations used to show spectral index roll-off in Figure 5.

the source a total size of $7''$, or 10.8 kpc. There is a component $0.5''$ southwest of the core that we refer to as the inner jet. The inner jet is most pronounced in the highest resolution 8 GHz image. The 15 GHz image, because taken in the VLA’s B configuration, does not resolve the inner jet as well despite the fact that it is our highest frequency.

Figures 3 and 4 show matched resolution spectral index maps of PKS 2322–123 in which α_{8377}^{14985} and α_{4985}^{14985} are measured, respectively. Both maps are overlaid with total intensity contours from the 14985 MHz image, and the color bar ranges from $\alpha = -3$ to $+1$. The northern and southern lobes have very steep spectra with typical values of $\alpha = -1.8$, which is slightly steeper than the spectral index of -1.5 previously observed by Sarazin et al. (1995). The core and inner jet both have flatter spectra with typical values in the core ranging from $\alpha = -1.2$ to -0.2 depending on the frequencies. It is interesting to note in Figure 3 that the spectrum flattens in the southern region of the southern lobe. The flattening is visible, but less pronounced in Figure 4. No significant flattening of the spectrum occurs in the northern lobe. The cross and triangle symbols plotted over the spectral index maps mark the total intensity centroid positions of the core and inner jet. The square and diamond symbols mark four positions chosen for comparison in the northern and southern lobes. These symbols are used in Figure 5 to show the difference in flux densities at our three observing bands; in each of the four plots the spectral

Figure 4. Spectral index map made from 4985 MHz and 14985 MHz. The colorbar ranges from $\alpha_{4985}^{14985} = -3$ to $+1$. Overlaid contours show total intensity at 14985 MHz. Solid contours start at $0.4 \text{ mJy beam}^{-1}$ and increase by factors of 2. Dashed contours represent $-0.4 \text{ mJy beam}^{-1}$. The peak contour flux is $43.1 \text{ mJy beam}^{-1}$. The restoring beam is a circular Gaussian with a FWHM of $0.5''$. The overlaid symbols (square, diamond, triangle, and cross) mark the locations used to show spectral index roll-off in Figure 5.

index is given by the slope of the segmented line. There appears to be no roll-off in the spectral index at low or high frequencies. Note that our 5 GHz, 8 GHz, and 15 GHz observations were taken in 1991, 1994, and 1996, respectively, so that the apparent dip in the spectral index plot of the compact core component may be due to source variability on a time scale of 3 years.

Figure 6 shows the rotation measure distribution created from 7815, 8165, 8515, and 8885 MHz. The color bar ranges from RM values of 800 rad m^{-2} to 6800 rad m^{-2} . Pixels with an error in the χ map of greater than 20° for any of the four frequencies have been flagged, and pixels corresponding to source locations with less than $200 \mu\text{Jy beam}^{-1}$ of total intensity flux at 8165 MHz are not shown. The overlaid contour lines show total intensity at 8885 MHz. Note that the polarized flux only appears in a small region of the southern lobe. Figure 7 shows RM fits for two pixels located in the cluster of pixels in the southern lobe. The fits result in rotation measures of $3950 \pm 570 \text{ rad m}^{-2}$ and $3510 \pm 720 \text{ rad m}^{-2}$, which are typical values for this source. Using the 62 pixels clustered together in the southern lobe, and excluding four pixels due to bad RM fits, we produce a histogram of the rotation measure in Figure 8. The histogram shows a mean RM value of 3620 rad m^{-2} and dispersion of 1080 rad m^{-2} . Because we have only 62 unflagged pixels in our RM map spanning about two beam widths, we consider there to be only one coherent area of the source with an RM

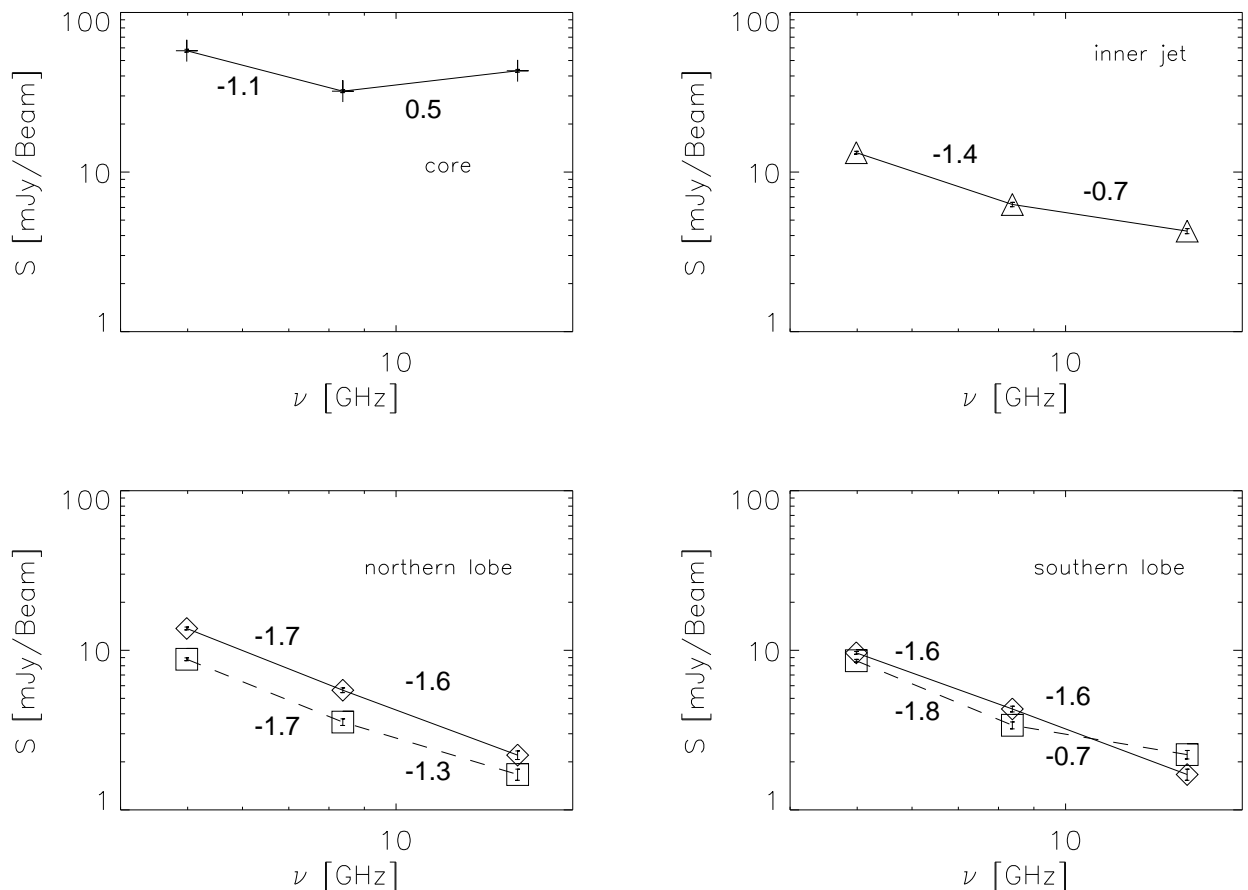

Figure 5. Log-log plot of flux density versus frequency at 4985, 8377, and 14985 MHz for six different source locations. (8377 MHz represents an average of the 6 X band frequencies used to calculate the spectral index, and 14985 MHz is an average of the 2 U band frequencies.) The slope of the segmented line gives two spectral indices, α_{4985}^{8377} and α_{8377}^{14985} . The values of α are shown next to each segmented line. The symbols used (square, diamond, triangle, and cross) correspond to the symbols plotted in Figure 3 and 4 which mark the position on the source used in this spectral index analysis. The error bars shown are much smaller than plotted symbols, and represent the RMS noise in the flux density maps and the 2% accuracy of the VLA.

value, namely the mean value. Although an RM dispersion of ~ 1000 rad m^{-2} is not atypical, due to the small number of clustered pixels in our histogram we do not consider this dispersion to be representative of the physical spread in RMs across the source. Instead, this dispersion most likely results from our low signal and is due to errors in the RM determination which are estimated to be ~ 700 rad m^{-2} .

5 DISCUSSION

5.1 Magnetic Field Strengths and Topologies

At its high galactic latitude ($b = -64.85^\circ$), A 2597 is far from the plane of our galaxy, and at its location we expect galactic RMs of less than 30 rad m^{-2} (Simard-Normandin & Kronberg 1980). Therefore our observed RMs located at a projected distance of $2''$ from the cluster center are most likely the result of Faraday rotation from a magnetized cluster gas, or Faraday rotation from a magnetic field within the cD galaxy which is located at the center of the cluster. It is also possible that the RMs are

the result of interaction between the radio galaxy and the surrounding ICM (Bicknell et al. 1990), however with polarized flux over a region of only 5 kpc, it is difficult to determine which of these scenarios produces the dominant field. Based on similar findings of high RMs in cooling core clusters with embedded sources of very different morphologies (Carilli & Taylor 2002), we favor a cluster magnetic field interpretation.

5.1.1 A Uniform Cluster Magnetic Field

Assuming that the rotation measure is the result of a magnetized cluster gas, rotation measures can be related to the line-of-sight magnetic field, B_{\parallel} , by

$$RM = 812 \int_0^L n_e B_{\parallel} dl \text{ radians } m^{-2}, \quad (2)$$

where B_{\parallel} is measured in μG , n_e in cm^{-3} , dl in kpc, and the upper limit of integration, L , is the distance from the

Figure 6. Rotation measure image of PKS 2322–123 with contours of total intensity at 8885 MHz overlaid. The colorbar ranges from 800 to 6800 rad m^{-2} . Rotation measure fits were performed using 7815, 8165, 8515, and 8885 MHz data. Pixels corresponding to a total intensity of less than $200 \mu\text{Jy beam}^{-1}$ (shown). Contours start at $0.35 \text{ mJy beam}^{-1}$ and increase by factors of 2. The peak contour flux is $56.2 \text{ mJy beam}^{-1}$. The restoring beam is a Gaussian with a semimajor axis of $1.5''$, a semiminor axis of $1.0''$, and a position angle of 0° .

emitting source to the end of the path through the Faraday screen along the line of sight.

We can estimate the minimum magnetic field needed to produce our observed RMs by making the simplest assumptions of a constant electron density, n_0 , and a uniform magnetic field out to a distance of the core radius, r_c . Using the values calculated in §3, and setting the rotation measure equal to our mean observed RM of 3620 rad m^{-2} , we find $B_{\parallel} = 2.1 \mu\text{G}$. This is a lower limit on the magnetic field strength because any field reversal along the line of sight would require a larger magnetic field to produce the same observed RM. Note that for $r > r_c$ the density falls off as r^{-2} and, assuming flux conservation, the magnetic field scales with $n^{2/3}$. This results in the rotation measure scaling with $r^{-7/3}$ so that the contribution to the RM is dominated by the cluster center.

5.1.2 A Tangled Cluster Magnetic Field

A more realistic estimate of the magnetic field assumes random field reversals on the order of a coherence length. Although in figure 6 the RM values are purely positive so that field reversals are not apparent, from the patchiness of the RM distributions observed in other sources, magnetic fields ordered on scales of $\sim 5 \text{ kpc}$ are common (Carilli & Taylor 2002). Due to the small region of polarized intensity in PKS 2322–123 it is difficult to determine

a suitable cell size by estimating the coherence length in the RM map. Therefore we use a cell size of 5 kpc , a typical value for both cooling core and noncooling core clusters (Carilli & Taylor 2002). Using the relation derived by Felten (1996), we can estimate the magnetic field assuming our calculated density distribution that follows a β -profile, and a magnetic field topology with cells of constant size and magnetic field strength, but random orientation.

$$\sigma_{\text{RM}} = \frac{KB n_0 r_c^{1/2} l^{1/2}}{(1 + r^2/r_c^2)^{(6\beta-1)/4}} \sqrt{\frac{\Gamma(3\beta - 0.5)}{\Gamma(3\beta)}} \quad (3)$$

In this equation, l is the cell size in kpc, r is the distance (in kpc) of the radio source from the cluster center, Γ is the Gamma function, B is given in μG and is related to the component along the line of sight by $B = \sqrt{3}B_{\parallel}$, and K is a factor that depends on the location of the radio source along the line of sight through the cluster: $K=624 \text{ rad } \mu\text{G}^{-1}$ if the source is beyond the cluster and $K=441 \text{ rad } \mu\text{G}^{-1}$ if the source is halfway through the cluster. The parameters r_c , n_0 , and β are as described in §3. Using values given in §3 and in Table 2, and a cell size of 5 kpc , we estimate the cluster magnetic field to be $2.9 \mu\text{G}$. This estimate which makes use of a tangled magnetic field model gives a line-of-sight magnetic field of $B_{\parallel} = 1.7 \mu\text{G}$, in agreement with the previous field estimate which assumed a uniform field topology. The fact that these two magnetic field topologies yield similar line-of-sight magnetic field strengths does not suggest any preferred field topology. Rather, it is more likely that σ_{RM} used in Equation 3 above is not a robust measurement of the true RM dispersion since the region covered is only a few beamwidths and the SNR is low. The dispersion is probably more indicative of the quality of the RM fit. Therefore, we conclude only that the cluster magnetic field has a minimum strength of $2.1 \mu\text{G}$. We note that this magnetic field strength is somewhat lower than the 5 to $10 \mu\text{G}$ typically found in cooling-core clusters (Carilli & Taylor 2002) which leads us to believe that a more complicated field topology is present, or that the RM dispersion has been underestimated.

5.2 The Nature of the Radio Source

The radio source PKS 2322–123 is located at the center of the galaxy cluster A 2597, and is coincident with a cD galaxy. Its small physical size, steep-spectrum lobes, and disturbed jet morphology all suggest the radio emission is confined by the ambient gas. This is similar to what is seen in the cluster center radio sources PKS 1246-410 in the Centaurus cluster (Taylor, Fabian, & Allen 2002), and PKS 0745-191 in the cluster of the same name (Taylor et al. 1994). The steep spectral indices of both the northern and southern lobes can be explained by a trapping of electrons such that low energy particles dominate the emission (Myers & Spangler 1985). In the past many people have classified A 2597 as a cooling-core cluster. Our analysis confirms the presence of a high central gas density in the cluster (Figure 1) and a short central cooling time; $t_{\text{cool}} < 10^9 \text{ yr}$ within $r \sim 30 \text{ kpc}$ of the central radio source.

The flattening of the spectral index in the southern part of the southern lobe may be caused by interactions between the radio jet and the surrounding ICM. As the jet moves south hitting the X-ray gas, some of the jet’s kinetic energy

Figure 7. Electric vector polarization angle versus square of wavelength at 4 frequencies in the 8 GHz observing band for two source locations. (left: RA $23^{\text{h}}25^{\text{m}}19^{\text{s}}.742$, Dec $-12^{\circ}07'29''.27$; right: RA $23^{\text{h}}25^{\text{m}}19^{\text{s}}.661$, Dec $-12^{\circ}07'28''.471$) Error bars show 1σ taken from the χ noise maps. Solid line is a least-squares-fit to the data. The slope of the solid line gives the rotation measure. For the eastern location, $\text{RM}=3950 \pm 570 \text{ rad m}^{-2}$; for the western location, $\text{RM}=3510 \pm 720 \text{ rad m}^{-2}$.

may reaccelerate the relativistic particles at the boundary layer, causing the spectrum to flatten. A similar situation may be responsible for the flatter spectrum of the northern radio lobe along its edge. To investigate this idea further we have constructed a 1 arcsec^2 pixel image from the X-ray data (reprocessed using relaxed screening criteria that exclude only the largest background flares, resulting in a net exposure time of 28ks). We first lightly smoothed this image, convolving it with a 1.2 arcsecond FWHM Gaussian kernel. This lightly smoothed image was then subtracted from a more heavily smoothed image, constructed by convolving the raw image with a $12 \text{ FWHM arcsecond}$ Gaussian kernel. The resulting unsharp-masked image is shown in Figure 9. The X-ray and radio peaks are nicely aligned without any correction to the X-ray position beyond the standard calibration. Enhanced X-ray emission is seen both along the northern edge of the northern lobe, and at the tip of the southern lobe – both regions where the spectral index is seen to flatten. In addition to this evidence of interaction between the radio jet and the ICM at the edges of the lobes, Koeke-moer et al. (1999) find $\text{H}\alpha$ emission-line filaments that trace the northern and southern lobes on the northwest and southeast edges, respectively. These edge-brightened arcs further suggest physical interactions at the boundary layer.

One explanation for the lack of detectable polarization in the northern lobe is that we have a greater Faraday depth towards this lobe, resulting in beamwidth depolarization. We calculate that at 8 GHz a Faraday rotation gradient of $\sim 350 \text{ rad m}^{-2} \text{ kpc}^{-1}$ is sufficient to rotate χ by 1 radian over our 2 kpc beam, thus causing depolarization over the beam width. This would require RMs on the order of 700 rad m^{-2} , 5 times lower than the observed RMs in the southern lobe. Thus Faraday depolarization can easily explain the lack of observed polarized flux in the northern lobe, and the low amounts of polarized flux in the southern lobe as well.

Two low density cavities were detected some 10s of arcseconds northeast and southwest of the radio core by McNamara (2001). These two cavities can be clearly seen in Figure 10. According to McNamara (2001) the low density cavities are at a projected distance of roughly 30 kpc from the center of the cluster. The X-ray cavities detected by McNamara et al. (2001) suggest some interesting jet movement. McNamara (2001) gives evidence supporting the idea that the cavities are associated with a radio outburst that occurred $50 - 100 \text{ Myr}$ ago. The recent discovery of 330 MHz radio emission in the western cavity by Clarke et al. (in prep) confirms the relic radio outburst theory. We suggest that the same radio jet that made the southern lobe in our

Figure 8. Rotation measure distribution for the 58 pixels clustered south of the core in Figure 6. (Four pixels have been discarded due to bad rotation measure fits.) The mean value is 3620 rad m^{-2} with dispersion of 1080 rad m^{-2} .

current observations was oriented southwest of the core in that previous radio episode and was deflected to the south at a later time. It is possible that as the relic radio bubble rose outward, the X-ray gas filling in the volume at low radii provided the additional pressure that caused the jet's deflection. VLBA observations of PKS 2322–123 show that on milliarcsecond scales the radio source is symmetric and has a northeast, southwest orientation (Taylor et al. 1999), providing further evidence that the southern jet begins in a southwesterly direction and is deflected to the south. Our observations of a bright inner jet southwest of the core (most easily seen in Figure 2b) are consistent with the VLBA observations and the theory of a deflected jet. The inner jet's relatively high flux density may be caused by interactions at the boundary layer at the deflection point. If the southern lobe of the radio source is propagating toward us, then we note that the observed angle through which the southern jet is deflected may be larger than the actual deflection angle due to projection effects. Finally, based on the detection of HI absorption toward the core and northeastern inner jet by Taylor et al. (1999), we suggest a source morphology in which the southern, deflected jet is on the approaching side. The fact that HI was not detected toward the southwestern jet can be explained if the HI is in a torus around the core, and the southwestern jet is on the approaching side.

If our deflected jet scenario is correct, then we may expect to see a pressure imbalance between the thermal X-ray gas and non-thermal gas in the radio lobes. We might expect the X-ray gas to have equal or greater pressure than the non-thermal gas; this would be consistent with our analysis of a small, confined radio jet. But in fact, using a minimum energy condition described by Miley (1980), we calculate the minimum pressure of the radio source to be $\sim 1.4 \times 10^{-9}$

Figure 9. Unsharp masked image of the X-ray emission from the inner part of the A 2597 cluster at 1.1 arcsecond resolution, overlaid on the 5 GHz VLA image.

erg cm⁻³ in both the northern and southern lobes, and $\sim 7.0 \times 10^{-9}$ erg cm⁻³ in the inner jet. The lobe values are in rough agreement with our calculated X-ray gas pressure of $\sim 7 \times 10^{-10}$ erg cm⁻³ in the northern and southern lobes. However, the minimum pressure in the inner radio jet is approximately an order of magnitude larger than the X-ray gas pressure at that radius ($\sim 8 \times 10^{-10}$ erg cm⁻³ at $r \sim 1$ kpc). If our assumption of the minimum energy condition is incorrect, and equipartition cannot be assumed, then the radio lobes would have a higher pressure than that which we calculated. Dunn and Fabian (2004) find that though the assumption of equipartition is sometimes correct, often it fails for reasons not well understood.

An alternative theory to that of the deflected southern jet is a precessing radio jet as described by Gower et al. (1982). If precession rather than deflection is the cause of the misalignment between the X-ray cavity and southern radio lobe, then the inner jet we observe with the VLA and the symmetry observed with the VLBA are evidence that the jet has now returned to the orientation it was in 50 – 100 Myr ago.

6 CONCLUSIONS

We detect polarized emission from the southern lobe of the radio source PKS 2322–123, which is embedded in the cooling-core cluster A 2597. We calculate this region of polarized flux to have a Faraday rotation measure of 3620 rad m⁻², which is consistent with the high RMs observed in other embedded radio sources (Taylor et al. 1994; Carilli & Taylor 2002). Assuming both uniform and tangled magnetic field topologies, we use our calculated RMs to estimate a minimum cluster magnetic field of 2.1 μ G, which is low compared to the 5 – 10 μ G typically found in galaxy clusters using similar methods (Carilli & Taylor 2002). Because polarized flux was only detected over a very small (~ 3 kpc) region, we believe that our low cluster magnetic field estimate is due to an underestimate in the RM dispersion. Future, more sensitive observations made with the Expanded VLA should reveal more polarized flux, allowing us to better estimate the RM dispersion.

We show two spectral index maps in which we measure steep spectrum lobes with $\alpha = -1.8$ and a flatter spectrum core with α ranging from -1.2 to -0.2 depending on the frequencies. We suggest that the flattening could be due to a boundary layer interaction with the ISM of the host galaxy. Comparison with the Chandra X-ray observations on the arcsecond scale show some weak evidence for density enhancements at the positions where the radio spectral index flattens. Future low frequency radio observations are needed to test this interaction hypothesis. Low frequency observations will also be interesting to determine the spectral curvature; we see no roll-off in the spectral index at 5, 8, and 15 GHz.

Based on our comparison of our radio observations with previous X-ray (McNamara et al. 2001) and VLBA observations (Taylor et al. 1999), we advocate a source orientation and morphology in which the southern jet has been deflected south from its original southwestern orientation, and is on the approaching side. Future proper motion studies on milli-arcsecond scales could help determine whether this proposed

source orientation is correct. If the western VLBI jet is propagating toward us relativistically, then we would expect to see faster motions on that side due to relativistic effects.
