rizzo@slac.stanford.edu*

A brief pedagogical overview of the phenomenology of Z' gauge bosons is presented. Such particles can arise in various electroweak extensions of the Standard Model (SM). We provide a quick survey of a number of Z' models, review the current constraints on the possible properties of a Z' and explore in detail how the LHC may discover and help elucidate the nature of these new particles. We provide an overview of the Z' studies that have been performed by both ATLAS and CMS. The role of the ILC in determining Z' properties is also discussed.

1.1. Introduction: What is a Z' and What is It Not ?

To an experimenter, a Z' is a resonance, which is more massive than the SM Z , observed in the Drell-Yan process $pp(p\bar{p}) \rightarrow l^+l^- + X$, where $l=e, \mu$ and, sometimes, τ , at the LHC(or the Tevatron). To a theorist, the production mechanism itself tells us that this new particle is neutral, colorless and self-adjoint, *i.e.*, it is its own antiparticle. However, such a new state could still be interpreted in many different ways. We may classify these possibilities according to the spin of the excitation, *e.g.*, a spin-0 $\tilde{\nu}$ in R-parity violating SUSY¹, a spin-2 Kaluza-Klein(KK) excitation of the graviton as in the Randall-Sundrum(RS) model^{2,3}, or even a spin-1 KK excitation of a SM gauge boson from some extra dimensional model^{4,5} Another possibility for the spin-1 case is that this particle is the carrier of a new force, a new neutral gauge boson arising from an extension of the SM gauge group, *i.e.*, a true Z' , which will be our subject below⁶. Given this discussion it is already clear that once a new Z' -like resonance is discovered it will first be necessary to measure its spin as quickly as possible to have some idea what

*Invited Talk presented at Theoretical Advanced Summer Institute 2006,
1-30 June 2006, Boulder, CO*

kind of new physics we are dealing with. As will be discussed below this can be done rather easily with only a few hundred events by measuring the dilepton angular distribution in the reconstructed Z' rest frame. Thus, a Z' is a neutral, colorless, self-adjoint, spin-1 gauge boson that is a carrier of a new force. ^a.

Once found to be a Z' , the next goal of the experimenter will be to determine as well as possible the couplings of this new state to the particles (mainly fermions) of the SM, *i.e.*, to *identify* which Z' it is. As we will see there are a huge number of models which predict the existence of a Z' ^{6,8}. Is this new particle one of those or is it something completely new? How does it fit into a larger theoretical framework?

1.2. Z' Basics

If our goal is to determine the Z' couplings to SM fermions, the first question one might ask is ‘How many fermionic couplings does a Z' have?’ Since the Z' is a color singlet its couplings are color-diagonal. Thus(allowing for the possibility of light Dirac neutrinos), in general the Z' will have 24 distinct couplings—one for each of the two-component SM fields: $u_{L_i}, d_{L_i}, \nu_{L_i}, e_{L_i} + (L \rightarrow R)$ with $i = 1 - 3$ labeling the three generations. (Of course, exotic fermions not present in the SM can also occur but we will ignore these for the moment.) For such a generic Z' these couplings are *non-universal*, *i.e.*, family-dependent and this can result in dangerous flavor changing neutral currents(FCNC) in low-energy processes. The constraints on such beasts are known to be quite strong from both $K - \bar{K}$ and $B_{d,s} - \bar{B}_{d,s}$ mixing⁹ as well as from a large number of other low-energy processes. There FCNC are generated by fermion mixing which is needed to diagonalize the corresponding fermion mass matrix. As an example, consider schematically the Z' coupling to left-handed down-type quarks in the weak basis, *i.e.*, $\bar{d}_{L_i}^0 \eta_i d_{L_i}^0 Z'$, with η_i being a set of coupling parameters whose different values would represent the generational-dependent couplings. For simplicity, now let $\eta_{1,2} = a$ and $\eta_3 = b$ and make the unitary transformation to the physical, mass eigenstate basis, $d_{L_i}^0 = U_{ij} d_{L_j}$. Some algebra leads to FCNC couplings of the type $\sim (b - a) \bar{d}_{L_i} U_{i3}^\dagger U_{3j} d_{L_j} Z'$. Given the existing experimental constraints, since we expect these mixing matrix elements to be of order those in the CKM matrix and a, b to be $O(1)$, the Z' mass must be huge, ~ 100 TeV or more, and outside the reach of the LHC. Thus un-

^aDistinguishing a Z' from a spin-1 KK excitation is a difficult subject beyond the scope of the present discussion⁷

less there is some special mechanism acting to suppress FCNC it is highly likely that a Z' which is light enough to be observed at the LHC will have *generation-independent* couplings, *i.e.*, now the number of couplings is reduced: $24 \rightarrow 8$ (or 7 if neutrinos are Majorana fields and the RH neutrinos are extremely heavy).

Further constraints on the number of independent couplings arise from several sources. First, consider the generator or ‘charge’ to which the Z' couples, T' . Within any given model the group theory nature of T' will be known so that one may ask if $[T', T_i] = 0$, with T_i being the usual SM weak isospin generators of $SU(2)_L$. If the answer is in the affirmative, then all members of any SM representation can be labeled by a common eigenvalue of T' . This means that u_L and d_L , *i.e.*, $Q^T = (u, d)_L$, as well as ν_L and e_L , *i.e.*, $L^T = (\nu, e)_L$ (and dropping generation labels), will have identical Z' couplings so that the number of independent couplings is now reduced from $8 \rightarrow 6(7 \rightarrow 5)$. As we will see, this is a rather common occurrence in the case of garden-variety Z' which originate from extended GUT groups⁶ such as $SO(10)$ or E_6 . Clearly, models which do not satisfy these conditions lead to Z' couplings which are at least partially proportional to the diagonal SM isospin generator itself, *i.e.*, $T' = aT_3$.

In UV completed theories a further constraint on the Z' couplings arises from the requirement of anomaly cancellation. Anomalies can arise from one-loop fermionic triangle graphs with three external gauge boson legs; recall that fermions of opposite chirality contribute with opposite signs to the relevant ‘VVA’ parts of such graphs. In the SM, the known fermions automatically lead to anomaly cancellation in a generation independent way when the external gauge fields are those of the SM. The existence of the Z' , together with gauge invariance and the existence of gravity, tells us that there are 6 new graphs that must also vanish to make the theory renormalizable thus leading to 6 more constraints on the couplings of the Z' . For example, the graph with an external Z' and 2 gluons tells us that the sum over the colored fermion’s eigenvalues of T' must vanish. We can write these 6 constraints as (remembering to flip signs for RH fields)

$$\begin{aligned}
 \sum_{\text{color triplets}, i} T'_i &= \sum_{\text{isodoublets}, i} T'_i = 0 & (1.1) \\
 \sum_i Y_i^2 T'_i &= \sum_i Y_i T_i'^2 = 0 \\
 \sum_i T_i'^3 &= \sum_i T'_i = 0,
 \end{aligned}$$

where here we are summing over various fermion representations. These 6 constraints can be quite restrictive, *e.g.*, if $T' \neq aT_{3L} + bY$, then even in the simplest Z' model, ν_R (not present in the SM!) must exist to allow for anomaly cancellation. More generally, one finds that the existence of new gauge bosons will also require the existence of other new, vector-like (with respect to the SM gauge group) fermions to cancel anomalies, something which happens automatically in the case of extended GUT groups. It is natural in such scenarios that the masses of these new fermions are comparable to that of the Z' itself so that they may also occur as decay products of the Z' thus modifying the various Z' branching fractions. If these modes are present then there are more coupling parameters to be determined.

1.3. Z-Z' Mixing

In a general theory the Z' and the SM Z are not true mass eigenstates due to mixing; in principle, this mixing can arise from two different mechanisms.

In the case where the new gauge group G is a simple new $U(1)'$, the most general set of $SU(2)_L \times U(1)_Y \times U(1)'$ kinetic terms in the original weak basis (here denoted by tilded fields) is

$$\mathcal{L}_K = -\frac{1}{4}W_{\mu\nu}^a W_a^{\mu\nu} - \frac{1}{4}\tilde{B}_{\mu\nu}\tilde{B}^{\mu\nu} - \frac{1}{4}\tilde{Z}'_{\mu\nu}\tilde{Z}'^{\mu\nu} - \frac{\sin\chi}{2}\tilde{Z}'_{\mu\nu}\tilde{B}^{\mu\nu}, \quad (1.2)$$

where $\sin\chi$ is a parameter. Here W_μ^a is the usual $SU(2)_L$ gauge field while $\tilde{B}_\mu, \tilde{Z}'_\mu$ are those for $U(1)_Y$ and $U(1)'$, respectively. Such gauge kinetic mixing terms can be induced (if not already present) at the one-loop level if $Tr(T'Y) \neq 0$. Note that if G were a nonabelian group then no such mixed terms would be allowed by gauge invariance. In this basis the fermion couplings to the gauge fields can be schematically written as $\bar{f}(g_L T_a W^a + g_Y Y \tilde{B} + \tilde{g}_{Z'} T' \tilde{Z}')f$. To go to the physical basis, we make the linear transformations $\tilde{B} \rightarrow B - \tan\chi Z'$ and $\tilde{Z}' \rightarrow Z'/\cos\chi$ which diagonalizes \mathcal{L}_K and leads to the modified fermion couplings $\bar{f}[g_L T_a W^a + g_Y Y B + g_{Z'}(T' + \delta Y)Z']f$ where $g_{Z'} = \tilde{g}_{Z'}/\cos\chi$ and $\delta = -g_Y \tan\chi/g_{Z'}$. Here we see that the Z' picks up an additional coupling proportional to the usual weak hypercharge. $\delta \neq 0$ symbolizes this gauge kinetic mixing¹⁰ and provides a window for its experimental observation. In a GUT framework, being a running parameter, $\delta(M_{GUT}) = 0$, but can it can become non-zero via RGE running at lower mass scales if the low energy sector contains matter in incomplete GUT representations. In most models¹⁰ where this happens, $|\delta(\sim TeV)| \leq 1/2$.

Z-Z' mixing can also occur through the conventional Higgs-induced SSB mechanism (*i.e.*, mass mixing) if the usual Higgs doublet(s), H_i (with vevs v_{D_i}), are *not* singlets under the new gauge group G. In general, the breaking of G requires the introduction of SM singlet Higgs fields, S_j (with vevs v_{S_j}). These singlet vevs should be about an order of magnitude larger than the typical doublet vevs since a Z' has not yet been observed. As usual the Higgs kinetic terms will generate the W, Z and Z' masses which for the neutral fields look like

$$\sum_i \left[\left(\frac{g_L}{c_w} T_{3L} Z + g_{Z'} T' Z' \right) v_{D_i} \right]^2 + \sum_j \left[g_{Z'} T' v_{S_j} Z' \right]^2, \quad (1.3)$$

where $c_w = \cos \theta_W$. (Note that the massless photon has already been 'removed' from this discussion.) The square of the first term in the first sum produces the square of the usual SM Z boson mass term, $\sim M_Z^2 Z^2$. The square of the last term in this sum plus the square of the second sum produces the corresponding Z' mass term, $\sim M_{Z'}^2 Z'^2$. However, the ZZ' interference piece in the first sum leads to Z-Z' mixing provided $T' H_i \neq 0$ for at least one i ; note that the scale of this cross term is set by the doublet vevs and hence is of order $\sim M_Z^2$.

This analysis can be summarized by noting that the interaction above actually generates a mass (squared) matrix in the ZZ' basis:

$$\mathcal{M}^2 = \begin{pmatrix} M_Z^2 & \beta M_Z^2 \\ \beta M_Z^2 & M_{Z'}^2 \end{pmatrix}. \quad (1.4)$$

Note that the symmetry breaking dependent parameter β ,

$$\beta = \frac{4c_w g_{Z'}}{g_L} \left[\sum_i T_{3L_i} T'_i v_{D_i}^2 \right] / \sum_i v_{D_i}^2, \quad (1.5)$$

can be argued to be O(1) or less on rather general grounds. Since this matrix is real, the diagonalization of \mathcal{M}^2 proceeds via a simple rotation through a mixing angle ϕ , *i.e.*, by writing $Z = Z_1 \cos \phi - Z_2 \sin \phi$, *etc.*, which yields the mass eigenstates $Z_{1,2}$ with masses $M_{1,2}$; given present data we may expect $r = M_1^2/M_2^2 \leq 0.01 - 0.02$. $Z_1 \simeq Z$ is the state presently produced at colliders, *i.e.*, $M_1 = 91.1875 \pm 0.0021$ GeV, and thus we might also expect that ϕ must be quite small for the SM to work as well as it does. Defining $\rho = M_Z^2/M_1^2$, with M_Z being the would-be mass of the Z if no mixing occurred, we can approximate

$$\begin{aligned} \phi &= -\beta r [1 + (1 + \beta^2)r + O(r^2)] \\ \delta\rho &= \beta^2 r [1 + (1 + 2\beta^2)r + O(r^2)], \end{aligned} \quad (1.6)$$

where $\delta\rho = \rho - 1$, so that β determines the sign of ϕ . We thus expect that both $\delta\rho, |\phi| < 10^{-2}$. In fact, if we are *not* dealing with issues associated with precision measurements¹¹ then Z-Z' mixing is expected to be so small that it can be safely neglected.

It is important to note that non-zero mixing modifies the predicted SM Z couplings to $\frac{g_L}{c_w}(T_{3L} - x_W Q)c_\phi + g_{Z'}T's_\phi$, where $x_W = \sin^2\theta_W$, which can lead to many important effects. For example, the partial width for $Z_1 \rightarrow f\bar{f}$ to lowest order (*i.e.*, apart from phase space, QCD and QED radiative corrections) is now given by

$$\Gamma(Z_1 \rightarrow f\bar{f}) = N_c \frac{\rho G_F M_1^3 (v_{eff}^2 + a_{eff}^2)}{6\sqrt{2}\pi}, \quad (1.7)$$

where N_c is a color factor, ρ is given above and

$$\begin{aligned} v_{eff} &= (T_{3L} - 2x_W Q)c_\phi + \frac{g_{Z'}}{g_L/(2c_w)}(T'_L + T'_R)s_\phi \\ a_{eff} &= T_{3L}c_\phi + \frac{g_{Z'}}{g_L/(2c_w)}(T'_L - T'_R)s_\phi, \end{aligned} \quad (1.8)$$

and where $T'_{L,R}$ are the eigenvalues of T' for $f_{L,R}$. Other effects that can occur include decay modes such as $Z_2 \rightarrow W^+W^-$, $Z_1 H_i$, where H_i is a light Higgs, which are now induced via mixing. If T' has no T_3 component this is the only way such decays can occur at tree level. In the case of the $Z_2 \rightarrow W^+W^-$ mode, an interesting cancellation occurs: the partial width scales as $s_\phi^2(M_2/M_W)^4$, where the second factor follows from the Goldstone Boson Equivalence Theorem¹². However, since $s_\phi \simeq -\beta r$ and $r = M_1^2/M_2^2 \simeq M_Z^2/M_2^2$, we find instead that the partial width goes as $\sim \beta^2$ without any additional mass enhancement or suppression factors. The tiny mixing angle induced by small r has been offset by the large M_2/M_W ratio! In specific models, one finds that this small Z-Z' mixing leads to $Z_2 \rightarrow W^+W^-$ partial widths which can be comparable to other decay modes. Of course, $Z_2 \rightarrow W^+W^-$ can be also be induced at the one-loop level but there the amplitude will be suppressed by the corresponding loop factor as well as possible small mass ratios.

1.4. Some Sample Z' Models

There are many (hundreds of) models on the market which predict a Z' falling into two rather broad categories depending on whether or not they arise in a GUT scenario. The list below is *only* meant to be representative

and is very far from exhaustive and I beg pardon if your favorite model is not represented.

The two most popular GUT scenarios are the Left Right Symmetric Model(LRM)¹³ and those that come from E_6 grand unification⁶.

(i) In the E_6 case one imagines a symmetry breaking pattern $E_6 \rightarrow SO(10) \times U(1)_\psi \rightarrow SU(5) \times U(1)_\chi \times U(1)_\psi$. Then $SU(5)$ breaks to the SM and only one linear combination $G = U(1)_\theta = c_\theta U(1)_\psi - s_\theta U(1)_\chi$ remains light at the TeV scale. θ is treated as a free parameter^b and the particular values $\theta = 0, -90^\circ, \sin^{-1} \sqrt{(3/8)} \simeq 37.76^\circ$ and $-\sin^{-1} \sqrt{(5/8)} \simeq -52.24^\circ$, correspond to ‘special’ models called ψ, χ, η and I , respectively. These models are sometimes referred to in the literature as effective rank-5 models(ER5M). In this case, neglecting possible kinetic mixing,

$$g_{Z'T'} = \lambda \frac{g_L}{c_w} \sqrt{\frac{5x_W}{3}} \left(\frac{Q_\psi c_\theta}{2\sqrt{6}} - \frac{Q_\chi s_\theta}{2\sqrt{10}} \right), \quad (1.9)$$

where $\lambda \simeq 1$ arises from RGE evolution. The parameters $Q_{\psi,\chi}$ originate from the embeddings of the SM fermions into the fundamental **27** representation of E_6 . A detailed list of their values can be found in the second paper in⁶ with an abbreviated version given in the Table below in LH field notation. Note that this is the *standard* form for this embedding and there are other possibilities⁶. These other choices can be recovered by a shift in the parameter θ . Note further that in addition to the SM fermions plus the RH neutrino, E_6 predicts, per generation, an additional neutral singlet, S^c , along with an electric charge $Q = -1/3$, color triplet, vector-like isosinglet, h , and a color singlet, vector-like isodoublet whose top member has $Q = 0$, H (along with their conjugate fields). These exotic fermions with masses comparable to the Z' cancel the anomalies in the theory and can lead to interesting new phenomenology⁶ but we will generally ignore them in our discussion below. In many cases these states are quite heavy and thus will not participate in Z' decays.

(ii) The LRM, based on the low-energy gauge group $SU(2)_L \times SU(2)_R \times U(1)_{B-L}$, can arise from an $SO(10)$ or E_6 GUT. Unlike the case of ER5M, not only is there a Z' but there is also a new charged W_R^\pm gauge boson since here $G = SU(2)$. In general $\kappa = g_R/g_L \neq 1$ is a free parameter but must be $> x_W/(1-x_W)$ for the existence of real gauge couplings. On occasions, the parameter $\alpha_{LR} = \sqrt{c_w^2 \kappa^2 / x_W^2 - 1}$ is also often used. In this case we

^bThe reader should be aware that there are several different definitions of this mixing angle in the literature, *i.e.*, $Z' = Z_\chi \cos \beta + z_\psi \sin \beta$ occurs quite commonly.

Table 1.1. Quantum numbers for various SM and exotic fermions in LH notation in E_6 models

Representation	Q_ψ	Q_χ
Q	1	-1
L	1	3
u^c	1	-1
d^c	1	3
e^c	1	-1
ν^c	1	-5
H	-2	-2
H^c	-2	2
h	-2	2
h^c	-2	-2
S^c	4	0

find that

$$g_{Z'T'} = \frac{gL}{c_w} [\kappa^2 - (1 + \kappa^2)x_W]^{-1/2} [x_W T_{3L} + \kappa^2(1 - x_W)T_{3R} - x_W Q]. \quad (1.10)$$

The mass ratio of the W' and Z' is given by

$$\frac{M_{Z'}^2}{M_{W'}^2} = \frac{\kappa^2(1 - x_W)\rho_R}{\kappa^2(1 - x_W) - x_W} > 1, \quad (1.11)$$

with the values $\rho_R = 1(2)$ depending upon whether $SU(2)_R$ is broken by either Higgs doublets (or by triplets). The existence of a $W' = W_R$ with the correct mass ratio to the Z' provides a good test of this model. Note that due to the LR symmetry we need not introduce additional fermions in this model to cancel anomalies although right-handed neutrinos are present automatically. In the E_6 case a variant of this model¹⁴ can be constructed by altering the embeddings of the SM and exotic fermions into the ordinary **10** and **5** representations (called the Alternative LRM, *i.e.*, ALRM).

(iii) The Z' in the Little Higgs scenario¹⁵ provides the best non-GUT example. The new particles in these models, *i.e.*, new gauge bosons, fermions and Higgs, are necessary to remove at one-loop the quadratic divergence of the SM Higgs mass and their natures are dictated by the detailed group structure of the particular model. This greatly restricts the possible couplings of such states. With a W' which is essentially degenerate in mass with the Z' , the Z' is found to couple like $g_{Z'T'} = (g_L/2)T_{3L} \cot \theta_H$, with θ_H another mixing parameter.

(iv) Another non-GUT example¹⁷ is based on the group $SU(2)_l \times SU(2)_h \times U(1)_Y$ with l, h referring to ‘light’ and ‘heavy’. The first 2 generations couple to $SU(2)_l$ while the third couples to $SU(2)_h$. In this case the Z’ and W’ are again found to be degenerate and the Z’ couples to $g_{Z'} T' = g_L [\cot \Phi T_{3l} - \tan \Phi T_{3h}]$ with Φ another mixing angle. Such a model is a good example of where the Z’ couplings are generation dependent.

(v) A final example is a Z’ that has couplings which are exactly the same as those of the SM Z (SSM), but is just heavier. This is not a real model but is very commonly used as a ‘standard candle’ in experimental Z’ searches. A more realistic variant of this model is one in which a Z’ has *no* couplings to SM fermions in the weak basis but the couplings are then induced in the mass eigenstate basis Z-Z’ via mixing. In this case the relevant couplings of the Z’ are those of the SM Z but scaled down by a factor of $\sin \phi$.

A nice way to consider rather broad classes of Z’ models has recently been described by Carena *et al.*¹⁸. In this approach one first augments the SM fermion spectrum by adding to it a pair of vector-like (with respect to the SM) fermions, one transforming like L and the other like d^c ; this is essentially what happens in the E_6 GUT model. The authors then look for families of models that satisfy the six anomaly constraints with generation-independent couplings. Such an analysis yields several sets of 1-parameter solutions for the generator T' but leaves the coupling $g_{Z'}$ free. The simplest such solution is $T' = B - xL$, with x a free parameter. Some other solutions include $T' = Q + xu_R$ (*i.e.*, $T'(Q) = 1/3$ and $T'(u_R) = x/3$ and all others fixed by anomaly cancellation), $T' = d_R - xu_R$ and $T' = 10 + x\bar{5}$, where ‘10’ and $\bar{5}$ refer to $SU(5)$ GUT assignments.

1.5. What Do We Know Now? Present Z’ Constraints

Z’ searches are of two kinds: indirect and direct. Important constraints arise from both sources at the present moment though this is likely to change radically in the near future.

1.5.1. Indirect Z’ Searches

In this case one looks for deviations from the SM that might be associated with the existence of a Z’; this usually involves precision electroweak measurements at, below and *above* the Z-pole. The cross section and forward backward asymmetry, A_{FB} , measurements at LEP II take place at

high center of mass energies which are still (far) below the actual Z' mass.

Since such constraints are indirect, one can generalize from the case of a new Z' and consider a more encompassing framework based on contact interactions¹⁹. Here one ‘integrates out’ the new physics (since we assume we are at energies below which the new physics is directly manifest) and express its influence via higher-dimensional (usually dim-6) operators. For example, in the dim-6 case, for the process $e^+e^- \rightarrow \bar{f}f$, we can consider an effective Lagrangian of the form¹⁹

$$\mathcal{L} = \mathcal{L}_{SM} + \frac{4\pi}{\Lambda^2(1 + \delta_{ef})} \sum_{ij=L,R} \eta_{ij}^f (\bar{e}_i \gamma_\mu e_i) (\bar{f}_j \gamma^\mu f_j), \quad (1.12)$$

where Λ is called ‘the compositeness scale’ for historic reasons, δ_{ef} takes care of the statistics in the case of Bhabha scattering, and the η ’s are chirality structure coefficients which are of order unity. The exchange of many new states can be described in this way and can be analyzed simultaneously. The corresponding parameter bounds can then be interpreted within your favorite model. This prescription can be used for data at all energies as long as these energies are far below Λ .

Z -pole measurements mainly restrict the Z - Z' mixing angle as they are sensitive to small mixing-induced deviations in the SM couplings and not to the Z' mass. LEP and SLD have made very precise measurements of these couplings which can be compared to SM predictions including radiative corrections¹¹. An example of this is found in Fig. 1.1 where we see the experimental results for the leptonic partial width of the Z as well as $\sin^2 \theta_{lepton}$ in comparison with the corresponding SM predictions. Deviations in $\sin^2 \theta_{lepton}$ are particularly sensitive to shifts in the Z couplings due to non-zero values of ϕ . Semiquantitatively these measurements strongly suggest that $|\phi| \leq a \text{ few } 10^{-3}$, at most, in most Z' models assuming a light Higgs. Performing a global fit to the full electroweak data set, as given, *e.g.*, by the LEPWWG¹¹ gives comparable constraints⁸.

Above the Z pole, LEP II data provides strong constraints on Z' couplings and masses but are generally insensitive to small Z - Z' mixing. Writing the couplings as $\sum_i \bar{f} \gamma_\mu (v_{f_i} - a_{f_i} \gamma_5) f Z_i^\mu$ for $i = \gamma, Z, Z'$, the differential cross section for $e^+e^- \rightarrow \bar{f}f$ when $m_f = 0$ is just

$$\frac{d\sigma}{dz} = \frac{N_c}{32\pi s} \sum_{i,j} P_{ij} [B_{ij}(1 + z^2) + 2C_{ij}z], \quad (1.13)$$

Fig. 1.1. Summer 2006 results from the LEPEWWG. (a) Fit for the Z leptonic partial width and $\sin^2 \theta_{\text{lepton}}$ in comparison to the SM prediction in the yellow band.(b) Comparison of a number of electroweak measurements with their SM fitted values.

where

$$B_{ij} = (v_i v_j + a_i a_j)_e (v_i v_j + a_i a_j)_f \quad (1.14)$$

$$C_{ij} = (v_i a_j + a_i v_j)_e (v_i a_j + a_i v_j)_f,$$

and

$$P_{ij} = s^2 \frac{(s - M_i^2)(s - M_j^2) + \Gamma_i \Gamma_j M_i M_j}{[(s - M_i^2)^2 + \Gamma_i^2 M_i^2][i \rightarrow j]}, \quad (1.15)$$

with \sqrt{s} the collision energy, Γ_i being the total widths of the exchanged particles and $z = \cos \theta$, the scattering angle in the CM frame. A_{FB} for any final state fermion f is then given by the ratio of integrals

$$A_{FB}^f = \left[\frac{\int_0^1 dz \frac{d\sigma}{dz} - \int_{-1}^0 dz \frac{d\sigma}{dz}}{\int_0^1 dz \frac{d\sigma}{dz} + \int_{-1}^0 dz \frac{d\sigma}{dz}} \right]. \quad (1.16)$$

If the e^\pm beams are polarized (as at the ILC but not at LEP) one can also

define the left-right polarization asymmetry, A_{LR}^f ; to this end we let

$$\begin{aligned} B_{ij} &\rightarrow B_{ij} + \xi(v_i a_j + a_i v_j)_e (v_i v_j + a_i a_j)_f \\ C_{ij} &\rightarrow C_{ij} + \xi(v_i v_j + a_i a_j)_e (v_i a_j + a_i v_j)_f, \end{aligned} \quad (1.17)$$

and then form the ratio

$$A_{LR}^f(z) = P \left[\frac{d\sigma(\xi = +1) - d\sigma(\xi = -1)}{\begin{array}{c} \text{"} \\ + \\ \text{"} \end{array}} \right], \quad (1.18)$$

where P is the effective beam polarization.

For a given Z' mass and couplings the deviations from the SM can then be calculated and compared with data; since no obvious deviations from the SM were observed, LEP II¹¹ places 95% CL lower bounds on Z' masses of 673(481, 434, 804, 1787) GeV for the $\chi(\psi, \eta, \text{LRM}(\kappa = 1), \text{SSM})$ models assuming $\lambda = 1$. Note that since we are far away from the Z' pole these results are not sensitive to any particular assumed values for the Z' width as long as it is not too large.

The process $e^+e^- \rightarrow W^+W^-$ can also be sensitive to the existence of a Z' , in particular, in the case where there is some substantial Z - Z' mixing²⁰. The main reason for this is the well-known gauge cancellations among the SM amplitudes that maintains unitarity for this process as the center of mass energy increases. The introduction of a Z' with Z - Z' mixing induces tiny shifts in the W couplings that modifies these cancellations to some extent and unitarity is not completely restored until energies beyond the Z' mass are exceeded. As shown by the first authors in Ref.²⁰, the leading effects from Z - Z' mixing can be expressed in terms of two s -dependent anomalous couplings for the $WW\gamma$ and WWZ vertices, *i.e.*, $g_{WW\gamma} = e(1 + \delta_\gamma)$ and $g_{WWZ} = e(\cot\theta_W + \delta_Z)$ and inserting them into the SM amplitude expressions. The parameters $\delta_{\gamma,Z}$ are sensitive to the Z' mass, its leptonic couplings, as well as the Z - Z' mixing angle. In principle, the constraints on anomalous couplings from precision measurements can be used to bound the Z' parameters in a model dependent way. However, the current data from LEP II¹¹ is not precise enough to get meaningful bounds. More precise data will, of course, be obtained at both the LHC and ILC.

The measurement of the W mass itself can also provides a constraint on $\delta\rho$ since the predicted W mass is altered by the fact that $M_Z \neq M_{Z_1}$. Some algebra shows that the resulting mass shift is expected to be $\delta M_W = 57.6 \frac{\delta\rho}{10^{-3}}$ MeV. Given that M_W is within $\simeq 30$ MeV of the predicted SM value and the current size of theory uncertainties²¹, strongly suggests that

$\delta\rho \leq a$ few 10^{-3} assuming a light Higgs. This is evidence of small r and/or β if a Z' is actually present.

Below the Z pole many low energy experiments are sensitive to a Z' . Here we give only two examples: (i) The E-158 Polarized Moller scattering experiment²² essentially measures A_{LR} which is proportional to a coupling combination $\sim -1/2 + 2x_{eff}$ where $x_{eff} = x_W + \text{'new physics'}$. Here x_W is the running value of $\sin^2\theta_W$ at low Q^2 which is reliably calculable. For a Z' (assuming no mixing) the 'new physics' piece is just $\frac{-1}{\sqrt{2}G_F} \frac{g_{Z'}}{M_{Z'}^2} v'_e a'_e$, which can be determined in your favorite model. Given the data,²² $x_{eff} - x_W = 0.0016 \pm 0.0014$, one finds, *e.g.*, that $M_{Z_\chi} \geq 960\lambda$ GeV at 90% CL. (ii) Atomic Parity Violation (APV) in heavy atoms measures the effective parity violating interaction between electrons and the nucleus and is parameterized via the 'weak charge', Q_W , which is again calculable in your favorite model:

$$Q_W = -4 \sum_i \frac{M_Z^2}{M_{Z_i}^2} a_{e_i} [v_{u_i}(2Z + N) + v_{d_i}(2N + Z)], \quad (1.19)$$

$= -N + Z(1 - 4x_W) +$ a Z' piece, in the limit of no mixing; here the sum extends over all neutral gauge bosons. The possible shift, ΔQ_W , from the SM prediction then constrains Z' parameters. The highest precision measurements from Cs ¹³³ yield²³ $\Delta Q_W = 0.45 \pm 0.48$ which then imply (at 95% CL) $M_{Z_\chi} > 1.05\lambda$ TeV and $M_{Z_{LRM}} > 0.67$ TeV for $\kappa = 1$. Note that though both these measurements take place at very low energies, their relative cleanliness and high precision allows us to probe TeV scale Z' masses. Fig. 1.2 shows the predicted value of the running $\sin^2\theta_W$ ²⁵ together with the experimental results obtained from E-158, APV and NuTeV²⁴. The apparent $\sim 3\sigma$ deviation in the NuTeV result remains controversial but is at the moment usually ascribed to our lack of detailed knowledge of, *e.g.*, the strange quark parton densities and not to new physics.

1.5.2. Direct Z' Searches

In this case we rely on the Drell-Yan process at the Tevatron as mentioned above. The present lack of any signal with an integrated luminosity approaching $\sim 1 \text{ fb}^{-1}$ allows one to place a model-dependent lower bound on the mass of any Z' . The process $p\bar{p} \rightarrow l^+l^- + X$ at leading order arises from the parton-level subprocess $q\bar{q} \rightarrow l^+l^-$ which is quite similar to the $e^+e^- \rightarrow f\bar{f}$ reaction discussed above. The cross section for the inclusive process is described by 4 variables: the collider CM energy, \sqrt{s} , the invari-

Fig. 1.2. A comparison by E-158 of the predictions for the running value of $\sin^2 \theta_W$ with the results of several experiments as discussed in the text.

ant mass of the lepton pair, M , the scattering angle between the q and the l^- , θ^* , and the lepton rapidity in the lab frame, y , which depends on its energy(E) and longitudinal momentum(p_z): $y = \frac{1}{2} \log \left[\frac{E+p_z}{E-p_z} \right]$. For a massless particle, this is the same as the pseudo-rapidity, η . With these variables the triple differential cross section for the Drell-Yan process is given by ($z = \cos \theta^*$)

$$\frac{d\sigma}{dM dy dz} = \frac{K(M)}{48\pi M^3} \sum_q \left[S_q G_q^+ (1 + z^2) + 2A_q G_q^- z \right], \quad (1.20)$$

where K is a numerical factor that accounts for NLO and NNLO QCD corrections²⁶ as well as leading electroweak corrections²⁸ and is roughly of order $\simeq 1.3$ for suitably defined couplings,

$$G_q^\pm = x_a x_b \left[q(x_a, M^2) \bar{q}(x_b, M^2) \pm q(x_b, M^2) \bar{q}(x_a, M^2) \right], \quad (1.21)$$

are products of the appropriate parton distribution functions(PDFs), with $x_{a,b} = M e^{\pm y} / \sqrt{s}$ being the relevant momentum fractions, which are evaluated at the scale M^2 and

$$S_q = \sum_{ij} P_{ij}(s \rightarrow M^2) B_{ij}(f \rightarrow q) \quad (1.22)$$

$$A_q = \sum_{ij} P_{ij}(s \rightarrow M^2) C_{ij}(f \rightarrow q),$$

with B, C and P as given above. In order to get precise limits (and to measure Z' properties once discovered as we will see later), the NNLO QCD corrections play an important role²⁶ as do the leading order electroweak radiative corrections²⁸. Apart from the machine luminosity errors the largest uncertainty in the above cross section is due to the PDFs. For $M \lesssim 1$ TeV or so these errors are of order $\simeq 5\%$ ³⁰ but grow somewhat bigger for larger invariant masses: $\sim 15(25)\%$ ³¹ for $M = 3(5)$ TeV. As a point of comparison the corrected SM predictions for the W and Z production cross sections at the Tevatron are seen to agree with the data from both CDF and D0 at the level a few percent³².

It is somewhat more useful to perform some of the integrals above in order to make direct comparison with experimental data. To this end we define (for our LHC discussion below)

$$\frac{d\sigma^\pm}{dM dy} = \left[\int_0^{z_0} \pm \int_{-z_0}^0 \right] \frac{d\sigma}{dM dy dz}, \quad (1.23)$$

and subsequently

$$\frac{d\sigma^\pm}{dM} = \left[\int_{y_{min}}^Y \pm \int_{-Y}^{-y_{min}} \right] \frac{d\sigma^\pm}{dM dy}. \quad (1.24)$$

Here Y is cut representing the edge of the central detector acceptance ($\simeq 1.1$ for the Tevatron detectors and $\simeq 2.5$ for those at the LHC) with $z_0 = \min[\tanh(Y - |y|), 1]$ being the corresponding angular cut. y_{min} is a possible cut employed to define the Z' boost direction which we will return to below. As in the case of e^+e^- collisions above, one can define an $A_{FB}(M) = d\sigma^-/d\sigma^+$.

A Z' , being a weakly interacting beast, generally has a rather narrow width to mass ratio, *i.e.*, $\Gamma_{Z'}^2/M_{Z'}^2 \ll 1$; *e.g.*, in the case of the SM Z this ratio is $\simeq 10^{-3}$. This being the case, almost the entire Z' event rate comes from a rather narrow window of M values: $M \simeq M_{Z'} \pm 2\Gamma_{Z'}$, or so. In this limit we can approximate the resonance as a δ -function in M and drop all of the SM contributions to the sums above. In this case, pieces of the P_{ij} that go as, *e.g.*, $M^4/|(M^2 - M_{Z'}^2) + iM_{Z'}\Gamma_{Z'}|^2$ can be replaced by $\frac{\pi}{2}\delta(M - M_{Z'})\frac{M_{Z'}^2}{\Gamma_{Z'}}$, up to $\Gamma_{Z'}^2/M_{Z'}^2$ corrections, so that integrals over M can be performed analytically (since the integral over the PDFs is now just a constant factor). In such a limit, the contribution to the cross section for l^+l^- production from the Z' is just $\sigma_{Z'}B(Z' \rightarrow l^+l^-)$ with $\sigma_{Z'}$ being the integrated value of the cross section at $M = M_{Z'}$, *i.e.*, at the Z' peak, and B being the leptonic branching fraction of the Z' . This is called the Narrow

Fig. 1.3. Normalized leptonic angular distribution predicted from the decay of particles with different spin produced in $q\bar{q}$ annihilation. The dashed(solid,dotted) curves are for spin-0(2,1). The generated data corresponds to 1000 events in the spin-2 case.

Width Approximation(NWA). In a similar way, A_{FB} on the Z' pole in the NWA is just the ratio $d\sigma^-/d\sigma^+$ evaluated at $M_{Z'}$; note that this ratio does *not* depend upon what decay modes (other than leptonic) that the Z' might have. Also note that in the NWA, the continuum Drell-Yan background makes no contribution to the event rate. This is a drawback of the NWA since it is sometimes important to know the height of the Z' peak relative to this continuum to ascertain the Z' signal significance.

It is evident from the above cross section expressions that the Z' (as well as γ and Z) induced Drell-Yan cross section involves only terms with a particular angular dependence due to the spin-1 nature of the exchanged particles. In the NWA on the Z' pole itself the leptonic angular distribution is seen to behave as $\sim 1+z^2+8A_{FB}z/3$, which is typical of a spin-1 particle. If the Z' had not been a Z' but, say, a $\tilde{\nu}$ in an R-parity violating SUSY model¹ which is spin-0, then the angular distribution on the peak would have been z -independent, *i.e.*, flat(with, of course, $A_{FB} = 0$). This is quite different than the ordinary Z' case. If the Z' had instead been an RS graviton² with spin-2, then the $q\bar{q} \rightarrow l^+l^-$ part of the cross section would behave as $\sim 1-3z^2+4z^4$, while the $gg \rightarrow l^+l^-$ part would go as $\sim 1-z^4$, both parts also yielding $A_{FB} = 0$. These distributions are also quite distinctive. Fig. 1.3 shows an example of these (normalized) distributions and demonstrates that with less than a few hundred events they are very

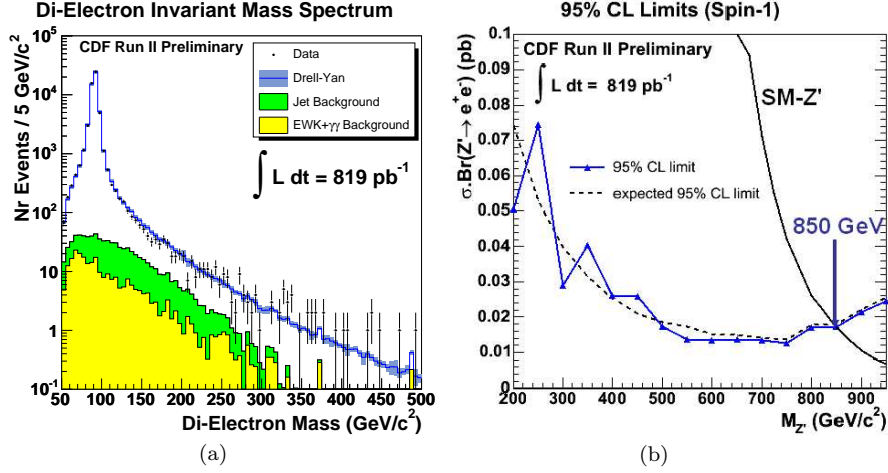

Fig. 1.4. (a) The Drell-Yan distribution as seen by CDF. (b) CDF cross section lower bound in comparison to the predictions for the Z' in the SSM.

easily distinguishable. Thus the Z' spin should be well established without much of any ambiguity given sufficient luminosity.

$E_6 Z'$ Model	Z_χ	Z_ψ	Z_η	Z_I	Z_N	Z_{sec}
Exp. limit (GeV/c ²)	735	725	745	650	710	675

Exp. $M_{Z'}$ limit (GeV/c ²)	625	765	835	910
Obs. $M_{Z'}$ limit (GeV/c ²)	625	760	830	900

(b)

Fig. 1.5. Experimental lower bounds from CDF on a number of Z' models: (a) E_6 models (b) Little Higgs models.

An important lesson from the NWA is that the signal rate for a Z' depends upon B , the Z' leptonic branching fraction. Usually in calculating B one assumes that the Z' decays only to SM fields. Given the possible existence of SUSY as well as the additional fermions needed in extended electroweak models to cancel anomalies this assumption may be wrong. Clearly Z' decays to these other states would decrease the value of B making the Z' more difficult to observe experimentally.

At the Tevatron only lower bounds on the mass of a Z' exist. These bounds are obtained by determining the 95% CL upper bound on the pro-

duction cross section for lepton pairs that can arise from new physics as a function of $M(= M_{Z'})$. (Note that this has a slight dependence on the assumption that we are looking for a Z' due to the finite acceptance of the detector.) Then, for any given Z' model one can calculate $\sigma_{Z'} B(Z' \rightarrow l^+ l^-)$ as a function of $M_{Z'}$ and see at what value of $M_{Z'}$ the two curves cross. At present the best limit comes from CDF although comparable limits are also obtained by D0³⁴. The left panel in Fig. 1.4 shows the latest (summer 2006) Drell-Yan spectrum from CDF; the right panel shows the corresponding cross section upper bound and the falling prediction for the Z' cross section in the SSM. Here we see that the lower bound is found to be 850 GeV *assuming* that only SM fermions participate in the Z' decay. For other models an analogous set of theory curves can be drawn and the associated limits obtained.

Fig. 1.5 shows the resulting constraints (from a different CDF analysis³⁵ with a lower integrated luminosity but also employing the A_{FB} observable above the mass of the SM Z) on a number of the models discussed above all assuming Z' decays to SM particles only and no Z - Z' mixing. Looking at these results we see that the Tevatron bounds are generally superior to those from LEP II and are approaching the best that the other precision measurements can do. These bounds would degrade somewhat if we allowed the Z' to have additional decay modes; for example, if B were reduced by a factor of 2 then the resulting search reach would be reduced by 50-100 GeV depending on the model.

The Tevatron will, of course, be continuing to accumulate luminosity for several more years possibly reaching as high as 8 fb^{-1} per experiment. Assuming no signal is found this will increase the Z' search reach lower bound somewhat, $\sim 20\%$, as is shown in Fig. 1.6 from³⁶. At this point the search reach at the Tevatron peters out due to the rapidly falling parton densities leaving the mass range above $\sim 1 \text{ TeV}$ for the LHC to explore.

1.6. The LHC: Z' Discovery and Identification

The search for a Z' at the LHC would proceed in the same manner as at the Tevatron. In fact, since the Z' has such a clean (*i.e.*, dilepton) signal and a sizable cross section it could be one of the first new physics signatures to be observed at the LHC even at relatively low integrated luminosities³⁷⁻³⁹. Fig. 1.7 shows both the theoretical anticipated 95% CL lower bound and the 5σ discovery reach for several different Z' models at the LHC for a single leptonic channel as the integrated luminosity is increased; these results are

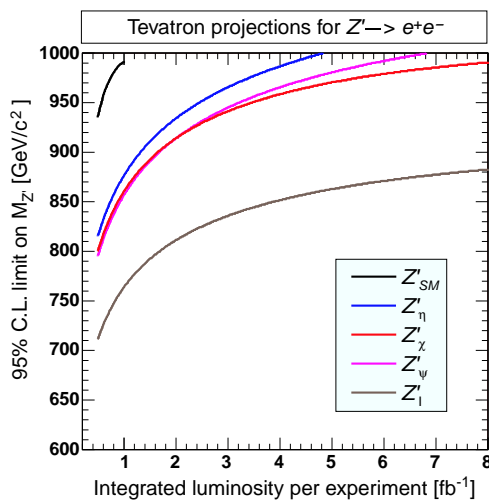

Fig. 1.6. Extrapolation of the Z' reach for a number of different models at the Tevatron as the integrated luminosity increases. Results from CDF and D0 are combined.

mirrored in detectors studies⁴⁰. Here we see that with only $10 - 20 \text{ pb}^{-1}$ the LHC detectors will clean up any of the low mass region left by the Tevatron below 1 TeV and may actually discover a 1 TeV Z' with luminosities in the $30 - 100 \text{ pb}^{-1}$ range! In terms of discovery, however, to get out to the $\sim 4 - 5$ TeV mass range will require $\sim 100 \text{ fb}^{-1}$ of luminosity. At such luminosities, the 95% CL bound exceeds the 5σ discovery reach by about 700 GeV. In these plots, we have again assumed that the Z' leptonic branching fraction is determined by decays only to SM fermions. Reducing B by a factor of 2 could reduce these reaches by $\simeq 10\%$ which is not a large effect.

The Z' peak at the LHC should be relatively easy to spot since the SM backgrounds are well understood as shown^{38,41} in Fig. 1.8 for a number of different Z' models. The one problem that may arise is for the case where the Z' width, $\Gamma_{Z'}$, is far smaller than the experimental dilepton pair mass resolution, δM . Typically in most models, $\Gamma_{Z'}/M_{Z'}$ is of order $\simeq 0.01$ which is comparable to dilepton pair mass resolution, $\delta M/M$, for both ATLAS⁴² and CMS⁴³. If, however, $\Gamma_{Z'}/M_{Z'} \ll \delta M/M$, then the Z' resonance is smeared out due to the resolution and the cross section peak is reduced by roughly a factor of $\sim \Gamma_{Z'}/\delta M$ making the state difficult to observe. This could happen, *e.g.*, if the Z' (before mixing with the SM Z) had no couplings to SM fields⁴⁴.

Given the huge mass reach of the LHC it is important to entertain the

Fig. 1.7. (a) 95% CL lower bound and (b) 5σ discovery reach for a Z' as a function of the integrated luminosity at the LHC for ψ (red), χ (green), η (blue), the LRM with $\kappa = 1$ (magenta), the SSM(cyan) and the ALRM(black). Decays to only SM fermions is assumed.

Fig. 1.8. Resonance shapes for a number of Z' models as seen by ATLAS assuming $M_{Z'} = 1.5$ TeV. The continuum is the SM Drell-Yan background.

question of how to ‘identify’ a particular Z' model once such a particle is found. This goes beyond just being able to tell the Z' of Model A from the Z' from model B. As alluded to in the introduction, if a Z' -like object is discovered, the first step will be to determine its spin. Based on the theoretical discussion above this would seem to be rather straightforward and studies of this issue have been performed by both ATLAS⁴⁵ and CMS⁴⁶.

Generally, one finds that discriminating a spin-1 or spin-2 object from one of spin-0 requires several times more events than does discriminating spin-2 from spin-1. The requirement of a few hundred events, however, somewhat limits the mass range over which such an analysis can be performed. If a particular Z' model has an LHC search reach of 4 TeV, then only for masses below $\simeq 2.5 - 3$ TeV will there be the statistics necessary to perform a reliable spin determination. Fig. 1.9 shows two sample results from this spin analysis. For the ATLAS study in the left panel⁴⁵ the lepton angular distribution for a weakly coupled 1.5 TeV KK RS graviton is compared with the expectation for a SSM Z' of identical mass assuming a luminosity of 100 fb^{-1} . Here one clearly sees the obvious difference and the spin-2 nature of the resonance. In the right panel⁴⁶ the results of a CMS analysis is presented with the distinction of a 1.5 TeV Z' and a KK graviton again being considered. Here one asks for the number of events(N) necessary to distinguish the two cases, at a fixed number of standard deviations, σ , which is seen to grow as (as it should) with \sqrt{N} . For example, a 3σ separation is seen to require $\simeq 300$ events.

Fig. 1.9. (a) The theoretical predictions for 1.5 TeV SSM Z' and RS graviton resonance shapes at ATLAS in comparison to the graviton signal data. (b) Differentiation, in σ , of spin-1 and spin-2 resonances at CMS as a function of the number of events assuming a 1.5 TeV mass.

Once we know that we indeed have a spin-1 object, we next need to ‘identify’ it, *i.e.*, uniquely determine its couplings to the various SM

fermions. (Note that almost all LHC experimental analyses up to now have primarily focused on being able to distinguish models and not on actual coupling extractions.) We would like to be able to do this in as model-independent a way as possible, *e.g.*, we should not assume that the Z' decays only to SM fields. Clearly this task will require many more events than a simple discovery or even a spin determination and will probably be difficult for a Z' with a mass much greater than $\simeq 2 - 2.5$ TeV unless integrated luminosities significantly in excess of 100 fb^{-1} are achieved (as may occur at the LHC upgrade⁴⁷). Some of the required information can be obtained using the dilepton (*i.e.*, e^+e^- and/or $\mu^+\mu^-$) discovery channel but to obtain more information the examination of additional channels will also be necessary.

Fig. 1.10. (a) A_{FB} near a 1.5 TeV Z' in a number of models. (b) On-peak differentiation of E_6 models using A_{FB} showing statistical errors for a 1.5 TeV Z' .

Table 1.2. Results on σ_{ll} and $\sigma_{ll} \times \Gamma_{Z'}$ for all studied models from ATLAS. Here one compares the input values from the generator with the reconstructed values obtained after full detector simulation.

		σ_{ll}^{gen} (fb)	σ_{ll}^{rec} (fb)	$\sigma_{ll}^{rec} \times \Gamma_{rec}$ (fb.GeV)
$M = 1.5 \text{ TeV}$	SSM	78.4 ± 0.8	78.5 ± 1.8	3550 ± 137
	ψ	22.6 ± 0.3	22.7 ± 0.6	166 ± 15
	χ	47.5 ± 0.6	48.4 ± 1.3	800 ± 47
	η	26.2 ± 0.3	24.6 ± 0.6	212 ± 16
	LR	50.8 ± 0.6	51.1 ± 1.3	1495 ± 72
$M = 4 \text{ TeV}$	SSM	0.16 ± 0.002	0.16 ± 0.004	19 ± 1
	KK	2.2 ± 0.07	2.2 ± 0.12	331 ± 35

In the dilepton mode, three obvious observables present themselves: (i)

the cross section, σ_{ll} , on and below the Z' peak (it is generally very small above the peak), (ii) the corresponding values of A_{FB} and (iii) the width, $\Gamma_{Z'}$, of the Z' from resonance peak shape measurements. Recall that while A_{FB} is B insensitive, both σ_{ll} and $\Gamma_{Z'}$ are individually sensitive to what we assume about the leptonic branching fraction, B , so that they cannot be used independently. In the NWA, however, one sees that the product of the peak cross section and the Z' width, $\sigma_{ll}\Gamma_{Z'}$, is *independent* of B . (Due to smearing and finite width effects, one really needs to take the product of $d\sigma^+/dM$, integrated around the peak and $\Gamma_{Z'}$.) Table 1.2 from an ATLAS study⁴⁸ demonstrates that the product $\sigma_{ll}\Gamma_{Z'}$ can be reliably determined at the LHC in full simulation, reproducing well the original input generator value.

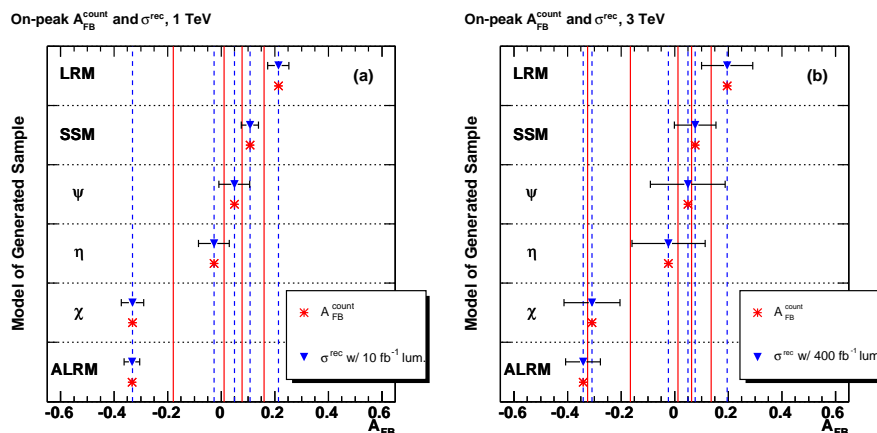

Fig. 1.11. CMS analysis of Z' model differentiation employing A_{FB} assuming $M_{Z'} = 1$ or 3 TeV.

Let us now consider the quantity A_{FB} . At the theory level, the angle θ^* employed above is defined to be that between the incoming q and the outgoing l^- . Experimentally, though the lepton can be charge signed with relative ease, it is not immediately obvious in which direction the initial quark is going, *i.e.*, to determine which proton it came from. However, since the q valence distributions are ‘harder’ (*i.e.*, have higher average momentum fractions) than the ‘softer’ \bar{q} sea partons, it is likely⁴⁹ that the Z' boost direction will be that of the original q . Of course, this is not *always* true so that making this assumption dilutes the true value of A_{FB} as does, *e.g.*,

additional gluon radiation. For the Z' to be boosted, the leptons in the final state need to have (significant) rapidity, hence the lower bound in the integration of the cross section expression above. Clearly, a full analysis needs to take these and other experimental issues into account.

Table 1.3. Measured on-peak A_{FB} for all studied models in the central mass bin from ATLAS. Here the raw value obtained before dilution corrections is labeled as ‘Observed’.

Model	$\int \mathcal{L}(fb^{-1})$	Generation	Observed	Corrected
1.5 TeV

LR	100	$+0.177 \pm 0.016$	$+0.100 \pm 0.026$	$+0.186 \pm 0.032$
4 TeV				
SSM	10000	$+0.057 \pm 0.023$	-0.001 ± 0.040	$+0.078 \pm 0.051$
KK	500	$+0.491 \pm 0.028$	$+0.189 \pm 0.057$	$+0.457 \pm 0.073$

The left panel of Fig. 1.10 shows⁵⁰ A_{FB} as a function of M in the region near a 1.5 TeV Z' for E_6 model η in comparison with the predictions of several other models. Here we see several features, the first being that the errors on A_{FB} are rather large except on the Z' pole itself due to relatively low statistics even with large integrated luminosities of $100 fb^{-1}$; this is particularly true above the resonance. Second, it is clear that A_{FB} both on and off the peak does show some reasonable model sensitivity as was hoped. From the right panel⁵⁰ of Fig. 1.10 it is clear that the various special case models of the E_6 family are distinguishable. This is confirmed by more detailed studies performed by both ATLAS⁴⁸ and CMS⁵¹. Fig. 1.11 from CMS⁵¹ shows how measurements of the on-peak A_{FB} can be used to distinguish models with reasonable confidence given sufficient statistics (and in the absence of several systematic effects). Table 1.3 from the ATLAS study⁴⁸ shows that the original input generator value of the on-peak A_{FB} can be reasonably well reproduced with a full detector simulation, taking dilution and other effects into account.

If a large enough on-peak data sample is available, examining A_{FB} as a function of the lepton rapidity⁵² can provide additional coupling information. The reason for this is that u and d quarks have different x distributions so that the weight of $u\bar{u}$ and $d\bar{d}$ induced Z' events changes as the rapidity varies. No detector level studies of this have yet been performed.

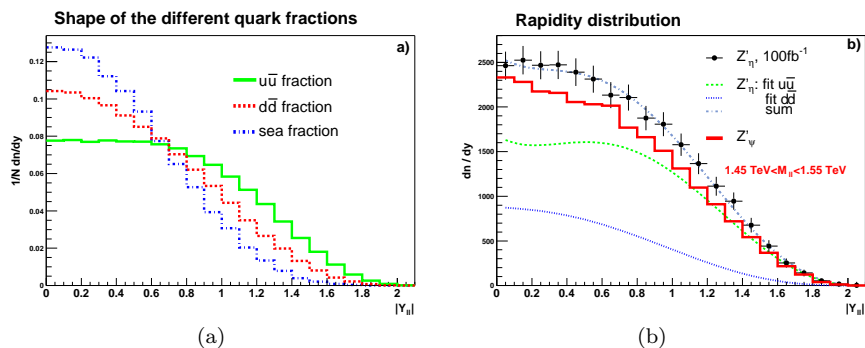

Fig. 1.12. (a) Rapidity distributions for different $q\bar{q}$ induced events. (b) Rapidity distribution differentiation of Z' models.

Off-peak measurements of A_{FB} are also useful although in this case systematics are more important; as shown in the ATLAS study⁴⁸, whose results are shown in Table 1.4, it is more difficult to reproduce the input generator value of this quantity than in the on-peak case.

Table 1.4. Measured off peak, $0.8 < M < 1.4 \text{ TeV}$, A_{FB} for all studied models from ATLAS using the same nomenclature as above.

Model	$\int \mathcal{L}(fb^{-1})$	Generation	Observed	Corrected
1.5 TeV				
SSM	100	$+0.077 \pm 0.025$	$+0.086 \pm 0.038$	$+0.171 \pm 0.045$
χ	100	$+0.440 \pm 0.019$	$+0.180 \pm 0.032$	$+0.354 \pm 0.039$
η	100	$+0.593 \pm 0.016$	$+0.257 \pm 0.033$	$+0.561 \pm 0.039$
ψ	100	$+0.673 \pm 0.012$	$+0.294 \pm 0.033$	$+0.568 \pm 0.039$
LR	100	$+0.303 \pm 0.022$	$+0.189 \pm 0.033$	$+0.327 \pm 0.040$

There are, of course, other observables that one may try to use in the dilepton channel but they are somewhat more subtle. The first possibility⁵⁰ is to reconstruct the Z' rapidity distribution from the dilepton final state. The left panel of Fig. 1.12 reminds us that the Z' rapidity distribution produced by only $u\bar{u}$, $d\bar{d}$ or sea quarks would have a different shape. The particular Z' couplings to quarks induce different weights in these three distributions and so one may hope to distinguish models in this way. An example of this is shown in the right panel of Fig. 1.12. The first analysis⁵⁰ of this type considered the quantity $R_{u\bar{u}}$, the fraction of Z' events originating from $u\bar{u}$, as an observable; a similar variable $R_{d\bar{d}}$ can also be constructed. Fig. 1.13 from a preliminary ATLAS analysis⁵³ compares the values of these two parameters extracted via full reconstruction for a 1.5 TeV Z' ; here we

see that reasonable agreement with the input values of the generator are obtained although the statistical power is not very good. Knowing both $R_{d\bar{d},u\bar{u}}$ and the ratio of the $d\bar{d}$ and $u\bar{u}$ parton densities fairly precisely, one can turn these measurements into a determination of the coupling ratio $(v'_u{}^2 + a'_u{}^2)/(v'_d{}^2 + a'_d{}^2)$.

Model	Generation level Fitted values (%)		Reconstruction level Fitted values (%)	
	Prop(Z'←dd)	Prop(Z'←uu)	Prop(Z'←dd)	Prop(Z'←uu)

LR	57.±4.	43.±14.	53.±13.	46.±15.

Fig. 1.13. Comparison of $R_{q\bar{q}}$ values determined at the generator level and after detector simulation by ATLAS.

A second possibility is to construct the rapidity ratio⁵⁴ in the region near the Z' pole:

$$R = \frac{\int_{-y_1}^{y_1} \frac{d\sigma}{dy} dy}{\left[\int_{y_1}^Y + \int_{-Y}^{-y_1} \frac{d\sigma}{dy} dy \right]}. \quad (1.25)$$

Here y_1 is some suitable chosen rapidity value $\simeq 1$. R essentially measures the ratio of the cross section in the central region to that in the forward region and is again sensitive to the ratio of u and d quark couplings to the Z' . A detector level study of this observable has yet to be performed.

In addition to the e^+e^- and $\mu^+\mu^-$ discovery channel final states, one might also consider other possibilities, the simplest being $\tau^+\tau^-$. Assuming universality, this channel does not provide anything new unless one can measure the polarization of the τ 's, P_τ , on or very near the Z' peak⁵⁵. The statistics for making this measurement can be rather good as the rate for this process is only smaller than that of the discovery mode by the τ pair reconstruction efficiency. In the NWA, $P_\tau = 2v'_e a'_e / (v'_e{}^2 + a'_e{}^2)$, assuming universality, so that the ratio of v'_e/a'_e can be determined uniquely. Fig. 1.14 shows, for purposes of demonstration, the value of P_τ in the E_6 model case where we see that it covers its fully allowed range.

Fig. 1.14. τ polarization asymmetry for a Z' in E_6 models in the NWA.

A first pass theoretical study⁵⁵ suggests that $\delta P_\tau \simeq 1.5/\sqrt{N}$, with N here being the number of reconstructed τ events. Even for a reconstruction efficiency of 3%, with $M_{Z'}$ not too large $\sim 1 - 1.5$ TeV, the high luminosity of the LHC should be able to tell us P_τ at the ± 0.05 level. It would be very good to see a detector study for this observable in the near future to see how well the LHC can really do in this case.

Once we go beyond the dileptons, the next possibility one can imagine is light quark jets from which one might hope to get a handle on the Z' couplings to quarks. The possibility of new physics producing an observable dijet peak at the LHC has been studied in detail by CMS⁵⁶; the essential results are shown in Fig. 1.15. Here we see that for resonances which are color non-singlets, *i.e.*, those which have QCD-like couplings, the rates are sufficiently large as to allow these resonances to be seen above the dijet background. However, for weakly produced particles, such as the SSM Z' shown here, the backgrounds are far too large to allow observation of these decays. Thus it is very unlikely that the dijet channel will provide us with any information on Z' couplings at the LHC.

Another possibility is to consider the heavy flavor decay modes, *i.e.*, $Z' \rightarrow b\bar{b}$ or $t\bar{t}$. Unfortunately, these modes are difficult to observe so that it will be quite unlikely that we will obtain coupling information from them. ATLAS⁵⁷ has performed a study of the possibility of observing these modes within the Little Higgs Model context for a Z' in the 1-2 TeV mass range.

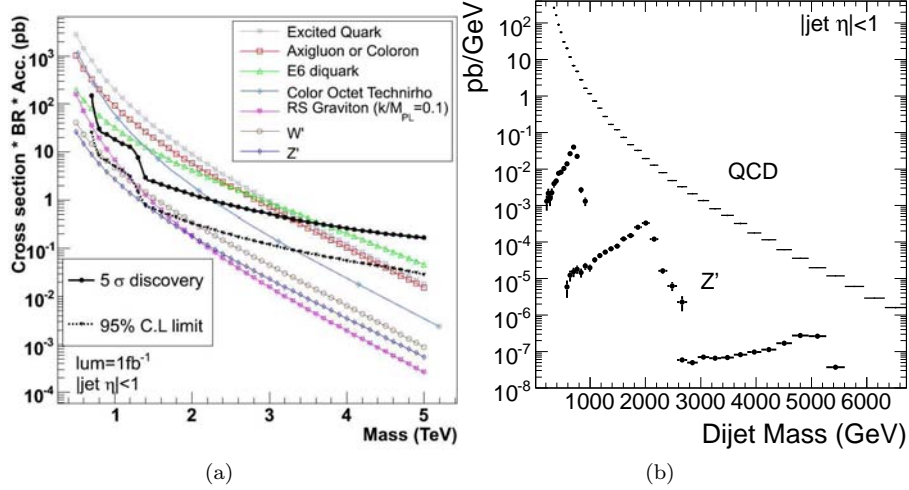

Fig. 1.15. (a) Dijet resonance discovery reach at CMS in comparison to the predictions for a number of models. (b) SSM Z' dijet signal for various masses in comparison with the SM background.

Fig. 1.16 from the ATLAS study demonstrates how difficult observing these decays may really be due to the very large SM backgrounds. It is thus unlikely that these modes will provide any important information except in very special cases.

Fig. 1.16. Search for heavy flavor decays of the Z' in the Little Higgs model by ATLAS. $\cot \theta_H = 1$ has been assumed. $Z' \rightarrow b\bar{b}$ assuming $M_{Z'} = 2$ TeV and a luminosity of 300 fb^{-1} (a) and $t\bar{t}$ (b) for $M_{Z'} = 1$ TeV and a luminosity of 30 fb^{-1} .

Another possible 2-body channel is $Z' \rightarrow W^+W^-$, which can occur at a reasonable rate through Z - Z' mixing as discussed above. Clearly the rate for this mode is very highly model dependent. ATLAS⁵⁸ has made a preliminary analysis of this mode in the $jjl\nu$ final state taking the Z' to be that of the SSM (for its fermionic couplings) and assuming a large integrated luminosity of 300 fb^{-1} . The mixing parameter β was taken to be unity in the calculations. The authors of this analysis found that a Z' in the mass range below $\simeq 2.2 \text{ TeV}$ could be observed in this channel given these assumptions. An example is shown in Fig. 1.17 where we clearly see the reconstructed Z' above the SM background. With a full detailed background study an estimate could likely be made of the relevant branching fraction in comparison to that of the discovery mode. This would give important information on the nature of the Z' coupling structure. More study of this mode is needed.

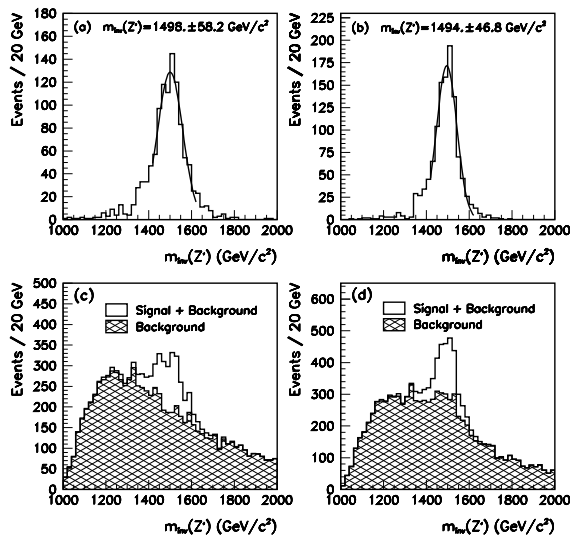

Fig. 1.17. Results of two ATLAS analyses showing the $Z' \rightarrow WW$ signal above SM backgrounds and Z' mass reconstruction in this channel for the SSM model assuming $M_{Z'} = 1.5 \text{ TeV}$ and $\beta = 1$.

A parallel study was performed by ATLAS⁴¹ for the $Z' \rightarrow ZH$ mode which also occurs through mixing as discussed above; this mixing occurs

naturally in the Little Higgs model in the absence of T-parity. The results are shown in Fig. 1.18. Here we see that there is a respectable signal over background and the relevant coupling information should be obtainable provided the Z' is not too heavy.

Fig. 1.18. Search study for the decay $Z' \rightarrow ZH$ by ATLAS in the Little Higgs model assuming $\cot \theta_H = 0.5$ for the $l^+l^-b\bar{b}$ mode assuming $M_{Z'}=1$ (a) or 2(b) TeV.

Some rare decays of the Z' may be useful in obtaining coupling information provided the Z' is not too massive. Consider the ratios of Z' partial widths^{54,59–61}

$$r_{ff'V} = \frac{\Gamma(Z' \rightarrow ff'V)}{\Gamma(Z' \rightarrow l^+l^-)}, \quad (1.26)$$

where $V = Z, W$ and $ff' = l^+l^-, l^\pm\nu, \nu\bar{\nu}$, appropriately. The two $\Gamma(Z' \rightarrow f\bar{f}Z)$ (with $f = l, \nu$) partial widths originate from the bremsstrahlung of a SM Z off of either the f or \bar{f} legs and are rather to imagine. Numerically, one finds that for the case $f = l$, little sensitivity to the Z' couplings is obtained so it is not usually considered. Assuming that the SM ν 's couple in a left-handed way to the Z' , it is clear that $r_{\nu\nu Z} = K_Z v_\nu'^2 / (v_e'^2 + a_e'^2)$, where K_Z is a constant, model-independent factor for any given Z' mass. The signal for this decay is a (reconstructed) Z plus missing p_T with a Jacobean peak at the Z' mass.

$r_{l\nu W}$, on the otherhand, is more interesting; not only can the W be produced as a bremsstrahlung but it can also arise directly if a WWZ' coupling exists.

As we saw above this can happen if Z-Z' mixing occurs *or* it can happen if T' is proportional to T_{3L} . If there is no mixing and if T' has no T_{3L} component then one finds the simple relation $r_{l\nu W} = K_W v'_\nu / (v_e'^2 + a_e'^2)$, with K_W another constant factor. Note that now $r_{l\nu W}$ and $r_{\nu\nu Z}$ are proportional to one another and, since T' and T_{3L} commute, one also has $v_e' + a_e' = v'_\nu + a'_\nu = 2v'_\nu$ so that both $r_{l\nu W}$ and $r_{\nu\nu Z}$ are *bounded*, *i.e.*, $0 \leq r_{l\nu W} \leq K_W/2$ and $0 \leq r_{\nu\nu Z} \leq K_Z/2$. Thus, *e.g.*, in E_6 models a short analysis shows that the allowed region in the $r_{l\nu W}, r_{\nu\nu Z}$ plane will be a straight line beginning at the origin and ending at $K_W/2, K_Z/2$. Other common models will lie on this line, such as the LRM and ALRM cases, but some others, *e.g.*, the SSM, will lie elsewhere in this plane signaling the fact that T' contains a T_{3L} component. Fig. 1.19 from⁶¹ shows a plot of these parameters for a large number of models, the solid line being the just discussed E_6 case and 'S' the SSM result.

While the coupling information provided by these ratios is very useful, the Z' event rates necessary to extract them are quite high in most cases due to their small relative branching fractions. For a Z' much more massive than 1-2 TeV the statistical power of these observables will be lost.

A different way to get at the Z' couplings is to produce it in association with another SM gauge boson, *i.e.*, a photon⁶² or a W^\pm, Z ⁶³, with the Z' decaying to dileptons as usual. Taking the ratio of this cross section to that in the discovery channel, we can define the ratios

$$R_{Z'V} = \frac{\sigma(q\bar{q} \rightarrow Z'V)B(Z' \rightarrow l^+l^-)}{\sigma(q\bar{q} \rightarrow Z')B(Z' \rightarrow l^+l^-)}, \quad (1.27)$$

in the NWA with $V = \gamma, W^\pm$, or Z. (For the case $V = g$ there is little coupling sensitivity⁶²). Note that B trivially cancels in this ratio but it remains important for determining statistics. The appearance of an extra particle V in the final state re-weights the combination of couplings which appears in the cross section so that one can get a handle on the vector and axial-vector couplings of the initial u 's and d 's to the Z'. For example, in the simple case of $V = \gamma$, the associated parton level $q\bar{q} \rightarrow Z'\gamma$ cross section is proportional to $\sum_i Q_i^2 (v_i'^2 + a_i'^2)$ while the simple Z' cross section is proportional to $\sum_i (v_i'^2 + a_i'^2)$. Similarly, for the case $V = W$, the cross section is found to be proportional to $\sum_i (v_i' + a_i')^2$. Tagging the additional V , when $V \neq \gamma$, may require paying the price of leptonic branching fractions for the W and Z, which is a substantial rate penalty, although an analysis has not yet been performed. For the case of $V = \gamma$, a hard p_T cut on the γ will be required but otherwise the signature is very clean. All the ratios

Fig. 1.19. Predictions for the rare decay mode ratios for a number of different models assuming a 1 TeV Z' : 'L' is the LRM with $\kappa = 1$, 'S'=SSM, 'A'=ALRM, *etc.* The solid line is the E_6 case.

$R_{Z'V}$ are of order a few $\times 10^{-3}$ (or smaller once branching fractions are included) for a Z' mass of 1 TeV and (with fixed cuts) tend to grow with increasing $M_{Z'}$. For example, for a 1 TeV Z' in the E_6 model, the cross section times leptonic branching fraction for the $Z'\gamma$ final state varies in the range 0.65-1.6 fb, depending upon the parameter θ , assuming a photon p_T cut of 50 GeV. R_γ for this case is shown in Fig. 1.20. Generically, with 100 fb^{-1} of luminosity these ratios might be determined at the level of $\simeq 10\%$ for the $M_{Z'}=1$ TeV case but the quality of the measurement will fall rapidly as $M_{Z'}$ increased due to quickly falling statistics. For much larger masses these ratios are no longer useful. It is possible that the Tevatron will tell us whether such light masses are already excluded.

It is clear from the above discussion that there are many tools available at the LHC for Z' identification. However, many of these are only applicable if the Z' is relatively light. Even if all these observables are available it still remains unclear as to whether or not the complete set of Z' couplings can

Fig. 1.20. R_γ in E_6 models for a 1 TeV Z' employing a cut $p_T^\gamma > 50$ GeV.

be extracted from the data with any reliability. A detailed analysis of this situation has yet to be performed. We will probably need a Z' discovery before it is done.

1.7. ILC: What Comes Next

The ILC will begin running a decade or so after the turn on of the LHC. At that point perhaps as much as $\sim 1 ab^{-1}$ or more of integrated luminosity will have been delivered by the LHC to both detectors. From our point of view, the role of the ILC would then be to either extend the Z' search reach (in an indirect manner) beyond that of the LHC or to help identify any Z' discovered at the LHC⁶⁴.

Although the ILC will run at $\sqrt{s} = 0.5 - 1$ TeV, we know from our discussion of LEP Z' searches that the ILC will be sensitive to Z' with masses significantly larger than \sqrt{s} . Fig. 1.21⁶⁵ shows the search reach for various Z' models assuming $\sqrt{s} = 0.5, 1$ TeV as a function of the integrated luminosity both with and without positron beam polarization. Recall that the various final states $e^+e^- \rightarrow f\bar{f}$, $f = e, \mu, \tau, c, b, t$ can all be used simultaneously to obtain high Z' mass sensitivity. The essential observables employed here are $d\sigma/dz$ and $A_{LR}(z)$, which is now available since the e^- beam is at least 80% polarized. One can also measure the polarization of τ 's in the final state. This figure shows that the ILC will be sensitive to Z' masses in the range $(7 - 14)\sqrt{s}$ after a couple of years of design luminosity,

the exact value depending on the particular Z' model. Thus we see that it is relatively easy at the ILC to extend the Z' reach beyond the 5-6 TeV value anticipated at the LHC. Fig. 1.22 from⁶⁶ shows a comparison of the

Fig. 1.21. Z' search reach at a $\sqrt{s}=0.5$ TeV(a) or 1 TeV(b) ILC as a function of the integrated luminosity without (solid) or with (dashed) 60% positron beam polarization for models ψ (green), χ (red), SSM (magenta) and LRM with $\kappa = 1$ (blue).

direct Z' search reach at the LHC with the indirect reach at the ILC; note the very modest values assumed here for the ILC integrated luminosities. Here we see explicitly that the ILC has indirect Z' sensitivity beyond the direct reach of the LHC.

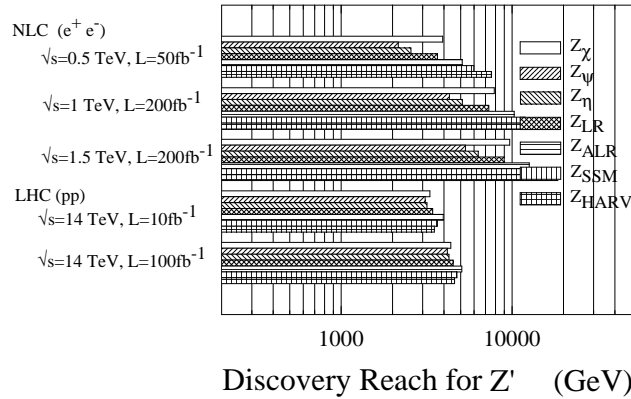

Fig. 1.22. A comparison of LHC direct and ILC indirect Z' search reaches.

In the more optimistic situation where a Z' is discovered at the LHC, the ILC will be essential for Z' identification. As discussed above, it is unclear whether or not the LHC can fully determine the Z' couplings, especially if it were much more massive than $\simeq 1$ TeV.

Once a Z' is discovered at the LHC and its mass is determined, we can use the observed deviations in both $d\sigma/dz$ and $A_{LR}(z)$ at the ILC to determine the Z' couplings channel by channel. For example, assuming lepton universality (which we will already know is applicable from LHC data), we can examine the processes $e^+e^- \rightarrow l^+l^-$ using $M_{Z'}$ as an input and determine both v'_e and a'_e (up to a two-fold overall sign ambiguity); a measurement of τ polarization can also contribute in this channel. With this knowledge, we can go on to the $e^+e^- \rightarrow b\bar{b}$ channel and perform a simultaneous fit to $v'_{e,b}$ and $a'_{e,b}$; we could then go on to other channels such as $c\bar{c}$ and $t\bar{t}$. In this way *all* of the Z' couplings would be determined. An example of this is shown in Fig. 1.23 from⁶⁷ where we see the results of the Z' coupling determinations at the ILC in comparison with the predictions of a number of different models.

1.8. Summary

The LHC turns on at the end of next year and a reasonable integrated luminosity ~ 1 fb^{-1} will likely be accumulated in 2008 at $\sqrt{s} = 14$ TeV. The community-wide expectation is that new physics of some kind will be seen relatively 'soon' after this (once the detectors are sufficiently well understood and SM backgrounds are correctly ascertained). Many new physics scenarios predict the existence of a Z' or Z' -like objects. It will then be up to the experimenters (with help from theorists!) to determine what these new states are and how they fit into a larger framework. In our discussion above, we have provided an overview of the tools which experiments at the LHC can employ to begin to address this problem. To complete this program will most likely require input from the ILC.

No matter what new physics is discovered at the LHC the times ahead should prove to be very exciting.

Acknowledgments
