ABSTRACT

When the afterglow fades at the site of a long-duration γ -ray burst (LGRB), Type Ic supernovae (SN Ic) are the only type of core collapse supernova observed. Recent work found that a sample of LGRB had different environments from a collection of core-collapse supernovae identified in a highredshift sample from colors and light curves. LGRB were in the brightest regions of their hosts, but the core-collapse sample followed the overall distribution of the galaxy light. Here we examine 263 fully spectroscopically-typed supernovae found in nearby (z < 0.06) galaxies for which we have constructed surface photometry from the Sloan Digital Sky Survey (SDSS). The distributions of the thermonuclear supernovae (SN Ia) and some varieties of core-collapse supernovae (SN II and SN Ib) follow the galaxy light, but the SN Ic (like LGRB) are much more likely to erupt in the brightest regions of their hosts. The high-redshift hosts of LGRB are overwhelmingly irregulars, without bulges, while many low redshift SN Ic hosts are spirals with small bulges. When we remove the bulge light from our low-redshift sample, the SN Ic and LGRB distributions agree extremely well. If both LGRB and SN Ic stem from very massive stars, then it seems plausible that the conditions necessary for forming SN Ic are also required for LGRB. Additional factors, including metallicity, may determine whether the stellar evolution of a massive star leads to a LGRB with an underlying broad-lined SN Ic, or simply a SN Ic without a γ -ray burst.

Subject headings: supernovae: general — gamma rays: bursts

1. INTRODUCTION

Type Ic supernovae (SN Ic) are defined by the absence of hydrogen, helium, and strong silicon features in their spectra. They are the only type of supernova observed after the fading of the afterglow from long-duration γ -ray bursts (Galama et al. 1998; Matheson et al. 2003; Stanek et al. 2003; Hjorth et al. 2003; Modjaz et al. 2006). SN Ic represent the extreme in a progression of increasing mass loss along the path to core collapse, ranging from SN II, which have hydrogen in their spectra (Filippenko 1997) through SN Ib, whose spectra lack hydrogen but show helium lines, to SN Ic which have neither hydrogen nor helium in their spectra. The three SN Ic firmly linked to LGRB events all had "broad-lined" spectral features, suggesting ejecta velocities on the order of 30,000 km/s. SN 1998bw was observed at the same position as a coincident LGRB (Galama et al. 1998); in the case of SN 2003dh, a residual SN Ic spectrum was discovered after subtracting a power-law continuum from the LGRB spectrum (Matheson et al. 2003; Stanek et al. 2003; Hjorth et al. 2003; and a SN spectrum was clear

in the follow-up spectra to the LGRB counterpart to SN 2006aj (Modjaz et al. 2006; Mirabal et al. 2006; Sollerman et al. 2006; Pian et al. 2006). Although our investigation is not tied to any particular theoretical picture, the qualitative features of "broad-lined" SN Ic are consistent with the collapsar picture that attributes LGRB to tightly collimated jets that emerge during core-collapse SN explosions (Woosley et al. 1993). In this case, the SN Ic spectrum suggests that the star has shed, or burned through deep mixing, much of its hydrogen and helium, making jet escape less difficult while the broad lines in the spectrum suggest that there are high velocities impressed on the bulk of the remaining gas.

Broad-lined SN Ic constitute a small fraction of the observed SN Ic population (Podsiadlowski et al. 2004; Guetta & Della Valle 2007). Because LGRB jets are inferred to be highly collimated, some fraction of broadlined SN Ic could be LGRB whose jets point in a direction that does not include Earth. From observations of radio emission that is assumed to be isotropic, the hypothesis in which all broad-lined SN Ic have off-axis jets was ruled out at the 84% confidence level (Soderberg et al. 2006), suggesting that poorly-aimed LGRB constitute only a modest percentage of the broad-lined events. Not all broad-lined SN Ic are associated with LGRBs or are especially luminous, and some broad-lined SN Ic-LGRB have computed energies similar to core-collapse SN (Mazzali et al. 2007), so broad-lined SN Ic are not

2 Kelly et al.

simply hyper-energetic or hyper-luminous SN Ic. In a small, but growing, sample, broad-lined SN Ic without an associated LGRB were found to inhabit more metal-rich galaxies than broad-lined SN Ic that have been associated with LGRB, pointing to metallicity as an important factor in determining whether a massive star produces a LGRB (Modjaz et al. 2007).

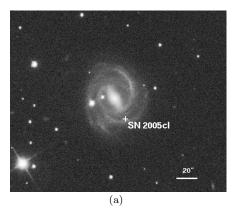

The study of LGRBs has used the locations of events in high redshift hosts to good effect (Bloom et al. 2002; Fruchter et al. 2006). In this paper, we use a technique developed by Fruchter et al. 2006 (F06) for use on distant LGRB host galaxies, applying it to the low-redshift SN host sample to establish the spatial distribution of supernova progenitors in this less exotic setting. Low-redshift SN Ib/SN Ic with host galaxies in the Sloan Digital Sky Survey (SDSS) were recently found to have more metalrich hosts and occur at somewhat smaller offsets from their hosts' centers than SN II (Prieto et al. 2007). F06 compared the positions of LGRBs to "core-collapse" SN discovered by the GOODS ACS Treasury Program (Riess et al. 2004; Strolger et al. 2004) with the mean redshift of LGRBs 1.25 and the mean redshift of SN 0.63. The Higher-Z team generally did not observe further any SN that did have not the colors of SN Ia. These rejects for cosmology ("Not SN Ia") constitute the F06 core-collapse sample. F06 found that core-collapse SN defined this way follow the light distributions of their hosts: the probability of a SN occurring in a given pixel is proportional to the counts in that pixel. LGRB positions, in contrast, were concentrated at the regions of highest surface brightness in their hosts. This is why F06 concluded that LGRB and core-collapse SN have different environments. In our nearby sample, we have the advantage of more complete spectroscopic information that permits a more refined sorting by supernova type.

2. DATA

Our sample was drawn from 3,184 SN discoveries reported to the International Astronomical Union (IAU) through 2005 August 27 collected in the Asiago Supernova Catalog (Barbon et al. 1999) as well as 17 more recently discovered SN Ib and Ic. We selected SN in hosts occurring inside SDSS DR6 coverage with z < 0.06. Typical galaxies in the sample, M-01-53-20 and NGC 2532, and the locations of SN 2005cl (Type IIn) and SN 2002hn (Type Ic) are shown in Figure 1.

2.1. Imaging

Although we assembled mosaics for galaxies that lay on the CCD chip edges, 9 SN with host galaxies (SN 1909A, SN 1951H, SN 1970G, SN 1971I, SN 1981K, SN 1993J, SN 1999gi, SN 2005bk, SN 2005cs) were so large that they were not used because the SDSS pipeline has difficulty with photometry in frames dominated by large galaxies. SN in the Asiago Supernova Catalog are reported with an associated host galaxy, and that host galaxy identification was assumed to be correct. Either from misreporting or problems with the image worldcoordinate system, host galaxy centers were inaccurate in the cases of 14 hosts (SN 1901B, SN 1988Y, SN 1990ag, SN 1991R, SN 1995ac, SN 1995T, SN 1995ah, SN 1995bc, SN 1997Y, SN 2001fv, SN 2004A, SN 2004fw, SN 2004hx) which were discarded. The images of six SN host galaxies included nearby bright stars that were impossible to

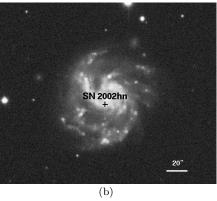

Fig. 1.— Typical galaxies in the sample. (a) SDSS g'-band image of size 0.7×0.7 arcmin² of the host galaxy M-01-53-20 for SN 2005cl, a SN IIn. (b) SDSS g'-band image of size 0.9×0.9 arcmin² of the host galaxy NGC 2532 for SN 2002hn, a SN Ic

mask out (SN 1980D, SN 1986E, SN 2001Z, SN 2003U, SN 2003eh, SN 2004co).

The SDSS (York et al. 2000) DR 6 (Adelman-McCarthy et al. 2007) includes 9583 square degrees of 53.9-second imaging in the Sloan filter set (u',g',r',i',z') on a wide-field 2.5 meter telescope in Apache Point, New Mexico. The Sloan filters partition the spectrum from the near-infrared detector sensitivity limit to the ultraviolet atmospheric cutoff in non-overlapping bands (Fukugita et al. 1996). Individual Sloan frames have a 2048 x 1498 array of 0.396" square pixels, creating a 13.5 x 9.9 arcminute field. Mean seeing values in our observations were the following: $u'1.62"\pm0.28"$; $g'1.53"\pm0.19"$; $r'1.42"\pm0.15"$; $i'1.43"\pm0.22"$; $i'1.35"\pm0.15"$.

3. METHODS

3.1. Fractional Flux

Our goal is to make measurements of the low-z sample to compare with the data presented by F06. We measure the surface brightness (1) in the pixel at the SN position and (2) by averaging inside a 0.4 kpc aperture centered at the SN position. We used SDSS g'-band images for comparison because the g'-band registers the spectral regions where galaxies emit most of the light detected by F06. Source Extractor (Bertin & Arnouts 1996) was used to find the set of pixels associated with the host galaxy light with signal-to-noise ratios greater than 1. From the distribution of pixel values in the galaxy light distribution and the local SN surface brightness measured in the pixel at the SN location, we calculate the "fractional"

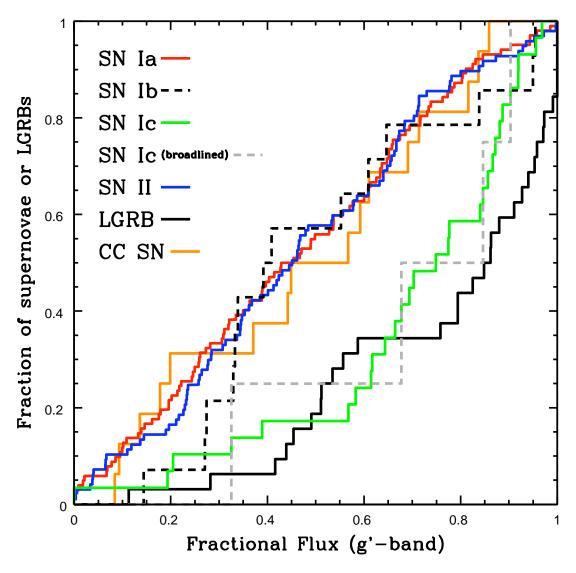

FIG. 2.— Low-redshift SN g'-band and high-redshift core-collapse SN and LGRB (from Fruchter et al. 2006) fractional flux distributions. SN Ic (N=29) (including broad-lined) are in brighter regions of their hosts than SN Ib (N=14) (p=0.018) and SN II (N=97) (p=0.0002). SN Ic are absent from the top 3% of galactic flux fraction distributions, which is likely due to the presence of bright central bulges and further explored in Figure 3. The SN Ib (N=14) distribution has an 8%, SN Ic distribution a 9%, and SN II (N=97) distribution only a 3×10^{-4} % probability of being drawn from the same set as LGRBs. The high redshift core-collapse sample, likely consisting predominantly of SN II, and SN II from our sample are highly similar (p = 0.90). SN Ia (N=102) are also similar to the SN II and the core-collapse (N=16) distributions, with p = 0.96 and p = 0.97 respectively.

flux." The fractional flux is the sum of counts registered in all pixels with fewer counts than measured at the SN location divided by the sum of all counts associated with the galaxy. This simple statistic allows a direct measurement of how SN events are distributed over their hosts. For galaxies with bulges, we make an additional calculation of the fractional flux after removing bulge light by replacing pixels values inside a circular region encompassing the bulge-dominated center with the mean of the perimeter pixel values.

$3.2. \ Residual \ SN \ Light$

From representative light curves (Cappellaro & Turatto 2001), we found that absolute magnitudes decay to fainter than -5 Johnson V magnitudes within one year for SN Ia, II except IIn, and Ib/Ic. We excluded SN when the SDSS observation of the host was made in the

time period ranging from 6 months before the supernova report through 24 months after detection. SN IIn sometimes show very slow luminosity evolution, so to avoid contamination, we excluded SN hosts with Sloan data taken over the range two years before detection to 5 years after the SN discovery. Converting SDSS magnitudes to Johnson V-band using kcorrect (v. 4.13), a SED fitting program developed for use with the SDSS filter set (Blanton et al. 2003), we found an absolute Johnson V magnitude of galaxy light in the pixel at the SN position of -8.81 \pm 2.04 for SN satisfying the previous time-selection criteria, roughly a factor of 30 times brighter than bright supernovae. These rules put us in a good position to avoid contamination of the galaxy surface brightness by light from the supernova.

4. RESULTS

4 Kelly et al.

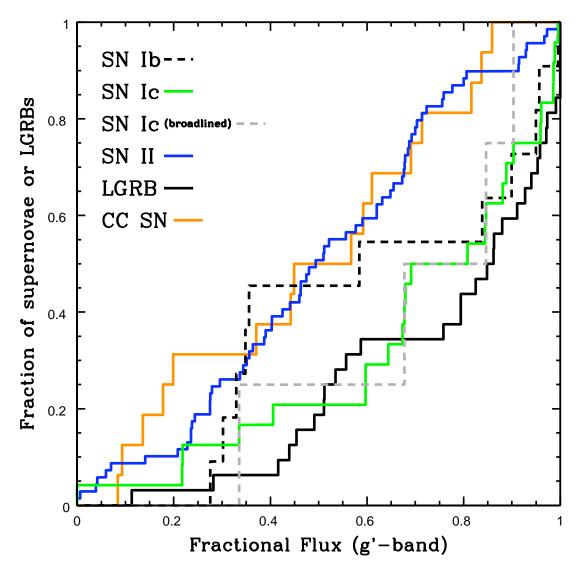

Fig. 3.— Bulge-subtracted low-redshift SN g'-band and high-redshift core-collapse SN and LGRB (from Fruchter et al. 2006) fractional flux distributions. After removing the bulge light that is present in low-redshift SN hosts but not the high-redshift and irregular LGRB hosts, there is a very high probability (p=0.86) that the SN Ic (N=24)(including broad-lined) and the LGRB (N=32) distributions are drawn from the same set. In contrast, it is highly unlikely that SN II (N=69) and LGRB are drawn from the same set (p=2x10⁻⁵). Bulge subtraction in SN II hosts does not strongly affect the SN II distribution, which remains linear and in good agreement with core-collapse SN (N=16) (p=0.56). There is a 12% probability that the SN Ib (N=11) distribution is identical to the LGRB distribution.

We plot the cumulative distribution of the "fractional flux" statistic in Figure 2: The Y-axis indicates the fraction of the supernova population with "fractional flux" values less than the X-axis value. If the population follows the light distribution, the "fractional flux" plot will be just a straight line connecting (0,0) and (1,1).

As can be seen in Figure 2, SN Ic are much more likely than SN Ib and SN II to be found in the brightest regions of their host galaxies. The distribution of the four "broad-lined" SN Ic in this Figure is consistent with the distribution of the larger SN Ic population. Broad-lined SN Ic are the type found at the sites of LGRB, but we have too few cases in our sample to say whether they track that distribution more closely than other SN Ic. In contrast to the strongly skewed SN Ic, the SN Ia, SN Ib, and SN II all have linear distributions with slopes of one that intersect the origin, indicating that they are evenly positioned throughout their hosts' light distribu-

tions. A Kolmogorov-Smirnov (KS) test finds a very low probability (p = 0.0002) that SN Ic (N=29) and SN II (N=97) are drawn from the same population, and low probability (p = 0.018) that SN Ic are drawn from the same population as SN Ib.

Figure 2 compares our fractional flux results for low redshift SN, all of which have spectroscopic types, to the results reported by F06 at high redshift. Both LGRB and SN Ic samples are concentrated in the bright regions of their hosts, in sharp contrast to SN II. We see good agreement between the "core-collapse" SN (N=16) from F06, which probably consists primarily of SN II and our low-redshift sample of SN II (N=97) (p = 0.90). If the observed ratio of (SN Ib + SN Ic)/SN II seen at low redshift is similar to that in the GOODS sample, then $\sim 1/5$ of the core-collapse sample will be SN Ib or SN Ic, the fraction found in nearby surveys (van den Bergh & Tammann 1991; Mannucci et al. 2005). Further, it is likely

that a number of SN Ib and SN Ic were mistaken for SN Ia on the basis of their colors. If the true connection of LGRB with core-collapse events is only with SN Ic, then this signal may well have been lost in the noise of a sample dominated by SN II. Unlike LGRBs, SN Ic are absent from the very brightest pixels in their hosts with no fractional flux values greater than 0.97. This difference may arise because the brightest few pixels in the low-redshift supernova galaxies are dominated by bulge light.

Because high-redshift LGRB hosts have no bulge component while some low-redshift hosts do, we subtract the bulge from our low-redshift hosts and remeasure fractional flux values. Figure 3 plots the fractional flux distributions for SN in hosts where we have removed bulge light by constructing a circular aperture encompassing the bulge and replacing enclosed pixel values by the mean of pixel values on the perimeter. We now find an 86% probability that the LGRB (N=32) and SN Ic (N=24) distributions could be drawn from a single underlying population. It remains highly unlikely that SN Ic and SN II (N=69) are drawn from the same set (p=0.005) and that SN II and LGRB are drawn from the same set (p= 2×10^{-6}).

SN were only included in Figure 3 if we could (1) visually identify and then subtract the bulge or (2) rule out a significant bulge. We therefore excluded bulgedominated and edge-on galaxies but included SN with dwarf galaxy hosts. The absolute magnitudes of the dwarf galaxy hosts are listed in Table 1. 11 of 14 SN Ib hosts and 24 of 29 SN Ic hosts either had their bulges removed or had no significant bulge and so were included in Figure 3.

To complement fractional flux, which measures the brightness at the SN or LGRB location relative to light across the entire host galaxy, Figure 4 plots surface brightnesses in the g'-band in a 400 parsec aperture at the SN location. SN Ic (N=20) locations have higher surface brightnesses than SN Ib (N=9) and SN II (N=94), with low probabilities (p = 0.068 and p=0.006) that they are drawn from the same population.

All data plotted in this paper is collected in Table 2.

5. SAMPLE COMPARISON

The low-z imaging used in this paper and the Hubble Space Telescope high-z data set used by F06 differ. A possible consequence is that the surface brightness cutoffs imposed by the S/N>1 requirement could be somewhat dissimilar. While it is beyond the scope of this paper to make a thorough exploration of the surface brightness in the two samples, there are good indicators suggesting that any such difference is not very significant.

Despite not correcting for $(1+z)^4$ cosmological dimming, F06 in fact found that fractional flux measurements for SN types and LGRB were not significantly different across the redshift range of their hosts from $z\sim0.3$ to $z\sim3$. F06 also varied their surface brightness threshold by a magnitude and found this had no significant effect on their results, a step we repeated in our data set with the same outcome. Almost no SN II in this paper or "core-collapse" SN in F06 have a zero fractional flux value despite the fact that their populations linearly follow their hosts' light distribution in both data sets, indicating that a high fraction of host light is captured in both data sets.

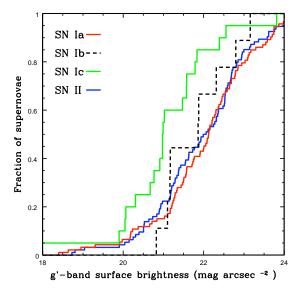

FIG. 4.— Surface g'-band brightnesses in 400 parsec apertures at the sites of SN. This plot shows that the g'-band surface brightnesses at SN Ic (N=20) sites are greater than those at SN Ib (N=9) and SN II (N=94) sites with p = 0.068 and p = 0.006. In contrast, there is a 77% probability that the SN Ib and SN II distributions are drawn from a single distribution.

The sizes of galaxies in this local sample and those studied in F06 differ, which may be partly attributed to the targeting biases in local SN searches toward luminous hosts. F06 measured the absolute Johnson V-band magnitudes and absolute sizes of galaxies, r_{80} , the elliptical semi-major axis containing 80% of the galactic light, using SExtractor and found that LGRB hosts were smaller than core-collapse (CC) SN hosts: CC SN 9.62 ± 5.58 and LGRB 3.36 ± 1.82 (kiloparsecs). We repeat these measurements for our sample: SN Ia 21.6 ± 13.1 ; SN II 19.48 ± 10.8 ; SN Ic 21.5 ± 10.0 ; and SN Ib 11.73 ± 2.75 (kiloparsecs).

6. CONCLUSIONS AND SUMMARY

SN Ic are generally found in the brightest parts of their host galaxies, a pattern that becomes even more extreme when only the star-forming disk population is considered. F06 has shown a similar result for LGRB in their irregular hosts, which lack bulges. These are presumably starforming regions where conditions are right for forming SN Ic and, in some cases, LGRB. A reasonable suggestion is that these are the places where the most massive stars form. In the case where stellar evolution branches in one direction, perhaps because of low abundance of heavy elements (Modjaz et al. 2007), the result may be a massive Wolf-Rayet star with no surface H or He, a compact envelope, and high angular momentum at the time of collapse that can become a LGRB (Yoon & Langer 2005; Woosley & Heger 2006). In more metal rich sites, stellar evolution takes another branch which results in a SN Ic that has similar chemistry of its atmosphere, but a less energetic core collapse. Whether it is the state of mass loss at the time of collapse or the energy release of the collapsing core that determines whether a star becomes a LGRB or a SN Ic remains to be established. It is interesting to speculate that the distribution of broadlined SN Ic in their hosts may have an even stronger connection to the sites of long γ -ray bursts and provide

6 Kelly et al.

a better understanding of the violent deaths of stars.

We especially thank P. Challis and M. Modjaz as well as T. Matheson, D. Mink, M. Blanton, W. Li, M. Hicken, J. Bloom, C. Blake, and S. Blondin for their help and expert advice. Research on SN at Harvard University is supported by the NSF by grant AST0606772. Additional funding for this work came through a summer grant from the Harvard College Research Program and the NSF under Grant No. PHY05-51164 to the Kavli Institute for Theoretical Physics. Work also supported in part by the U.S. Department of Energy under contract number DE-AC02-76SF00515.

Funding for the SDSS and SDSS-II has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Science Foundation, the U.S. Department of Energy, the National Aeronautics and Space Administration, the Japanese Monbukagakusho, the Max Planck Society, and the Higher Education Funding Council for England.

The SDSS is managed by the Astrophysical Research Consortium for the Participating Institutions. The Participating Institutions are the American Museum of Natural History, Astrophysical Institute Potsdam, University of Basel, Cambridge University, Case Western Reserve University, University of Chicago, Drexel University, Fermilab, the Institute for Advanced Study, the Japan Participation Group, Johns Hopkins University, the Joint Institute for Nuclear Astrophysics, the Kavli Institute for Particle Astrophysics and Cosmology, the Korean Scientist Group, the Chinese Academy of Sciences (LAMOST), Los Alamos National Laboratory, the Max-Planck-Institute for Astronomy (MPIA), the Max-Planck-Institute for Astrophysics (MPA), New Mexico State University, Ohio State University, University of Pittsburgh, University of Portsmouth, Princeton University, the United States Naval Observatory, and the University of Washington.

Note. — We list data values for the ambiguously typed SN Ib/Ic, even though they are not included in plots in the main text. Each SN type plotted in this Letter includes all subtypes and SN with peculiar ("pec") designations. These subtypes include broad-lined ("Ib-bl") for SN Ic and linear ("IIL"), plateau ("IIP"), with narrow emission lines ("IIn"), and the transitional type ("IIb") for SN II. A colon (":") indicates some uncertainty in the classification while an asterisk ("*") denotes classification made using a light curve.
