# HADRON PRODUCTION IN NUCLEAR COLLISIONS－ <br> A NEW PARTON MODEL APPROACH＊ <br> Stanley J。Brodsky <br> Stanford Linear Accelerator Center Stanford University，Stanford，California 94305 <br> John F。Gunion <br> Department of Physics <br> University of California，Davis，California 95616 <br> J。H。Kühn <br> Max Planck Institut für Physik und Astrophysik Munchen 40，Germany 

#### Abstract

We consider a simple quark－parton model for inelastic hadron－ nucleus interactions where the wee partons of the projectile－uncorre－－ lated in rapidity－interact with the wee partons of essentially inde－ pendent nucleons in the target．The ratio of multiplicitios in the central region is given by $$
\mathrm{R}_{\mathrm{A}}=\frac{\langle\mathrm{n}\rangle \mathrm{HA}}{\langle\mathrm{n}\rangle \mathrm{HN}}=\frac{\bar{\nu}}{2}+\frac{\bar{\nu}}{\bar{\nu}+1}
$$ where $\bar{\nu} \equiv \mathrm{A} \sigma_{\mathrm{HN}}^{\mathrm{inel}} / \sigma_{\mathrm{HA}}^{\mathrm{inel}}$ is the average number of inelastic collisions of the projectile $H$ in the nucleus．Including the effects of the leading par－ ticle regions，this prediction is in excellent agreement with experiment． Predictions are also given for multiplicity distributions in hadron－nucleus collisions and for multiplicities produced in nucleus－nucleus collisions． The model，which is consistent with Glauber theory，predicts the ab－ sence of shadowing at large $q^{2}$（independent of $\omega$ ）in electroproduction or whenever the momentum transfer of a subprocess is large．

（Submitted to Phys．Rev。Lett．）

[^0]Although the quark-parton model has been very successful in predicting the short tistance behavior of hadronic interactions, the underlying mechanisms involved in the production of hadrons in ordinary high energy collisions have never been specified. In the case of particle production on nuclear targets, this fundamental uncertainty of the parton approach becomes amplified, and this has led to an extraordinary range of divergent predictions for even the most basic experimental parameters. ${ }^{1}$ In this letter we present a new approach to this problem based on a straightforward application of parton model concepts. The resulting picture for nuclear collisions is very simple and in good agreement with experiment. It is based upon (1) the assumption that each inelastically excited nucleon in the nuclear target produces hadrons independently of the others, and (2) a specific hadronic collision model based on wee parton interactions ${ }^{2}$ analogous to the Drell-Yan ${ }^{3}$ pair production process.

We begin with a simple parton model description of hadron-hadron interactions. Each hadron has a Fock-space decomposition in terms of multiparton states. An interaction occurs via a collision of a parton in the beam (B) with a parton in the target (A). The cross section takes the typical Drell-Yan form ${ }^{3,4}$

$$
\sigma_{B A}=\sum_{\substack{a \in A \\ b \in B}} \int_{0}^{1} d x_{a} \int_{0}^{1} d x_{b} G_{a / A}\left(x_{a}\right) G_{b / B}\left(x_{b}\right) \hat{\sigma}_{a b}\left(\hat{\mathrm{~s}}_{a b}\right)
$$

where

$$
x_{b}=\left(k_{b}^{o}+k_{b}^{z}\right) /\left(p_{B}^{o}+p_{B}^{z}\right)
$$

and

$$
x_{a}=\left(k_{a}^{0}-k_{a}^{z}\right) /\left(p_{A}^{o}-p_{A}^{z}\right)
$$

are the light-cone fractions $\left(\mathrm{p}_{\mathrm{B}}^{\mathrm{Z}}>0, \mathrm{p}_{\mathrm{A}}^{\mathrm{Z}}<0\right)$ of the beam and target, respectively, and

$$
\hat{s}_{a b}=x_{a} x_{b} s+\frac{m_{a}^{2} m_{b}^{2}}{x_{a} x_{b} s}
$$

is the collision energy squared of the subprocess．（For simplicity we do not display the transverse momentum dependence。）Expression（1）is Lorentz－ invariant for boosts along the beam（ $z$ ）direction．We presume that $\hat{\sigma}_{a b}$ falls rapidly with increasing $\hat{\mathrm{s}}_{\mathrm{ab}}$ ，as would be typical of quark－parton exchange ${ }^{2,5}$ or $q-\bar{q}$ annihilation processes，${ }^{6}$ and that each distribution $G(x)$ has the Feynman ${ }^{2}$ wee parton distribution $\mathrm{xG}(\mathrm{x}) \rightarrow \mathrm{C} \neq 0$ at $\mathrm{x} \rightarrow 0$ 。 In this model $\sigma_{\mathrm{BA}}(\mathrm{s}) \propto \log \mathrm{s}$ ， and the location in rapidity of the parton－parton collision $\hat{y}$ is distributed uni－ formly throughout the central region，where neither $\mathrm{x}_{\mathrm{a}}$ nor $\mathrm{x}_{\mathrm{b}}$ is forced into the finite $x$ ，power－law damped regions of $G(x)$ 。 In inelastic collisions，the partons in the beam materialize as hadrons for $\hat{\mathrm{y}} \lesssim \mathrm{y}<\mathrm{Y}_{\mathrm{B}}$ ，and those in the target ma－ terialize throughout the interval $\mathrm{Y}_{\mathrm{A}}<\mathrm{y} \lesssim \hat{\mathrm{y}}$ 。 Note that real hadron production from the beam partons cannot extend much below $\hat{y}$ since this forces propagators off－shell where interactions are suppressed．

Turning to nuclear collisions，we shall assume that，aside from small bind－ ing corrections and Fermi motion effects，each nucleon in the nucleus indepen－ dently develops its own parton distribution．Thus the partons of different nu－ cleons interact with each other only minimally and do not shadow or coalesce with one another．${ }^{7}$ In a high energy collision the various wee partons of the projectile can interact with the wee partons of different nucleons．The rapidity locations of the parton－parton collisions $\hat{\mathrm{y}}_{\mathrm{i}}$ are uncorrelated and uniformly dis－ tributed in the central region．Each nucleon in the nucleus A participates in only one interaction，whereas the mean number of inelastic collisions of the beam hadron H is $\bar{\nu}=\mathrm{A} \sigma_{\mathrm{HN}}^{\text {inel }} / \sigma_{\mathrm{HA}}^{\text {inel }}$ ．On the average，then，the rapidity separa－ tion between parton collisions is $\Delta \mathrm{y} \cong \mathrm{Y}_{\mathrm{c}} /(\bar{\nu}+1)$ where $\mathrm{Y}_{\mathrm{c}}$ is the total length of
the central rapidity region。 A typical multiparticle distribution for $\bar{\nu}=3$ colli－ sions is illustrated in Fig。1。 Since the collision rapidities are uncorrelated， each inelastically excited nucleon produces hadronic multiplicity on the average halfway across the central region．As the number of collisions increases，the range of the projectile hadron distribution extends further and further into the central region to the minimum $\hat{y}_{i}$－on the average over a rapidity length $\bar{\nu} \Delta \mathrm{y}=(\bar{\nu} /(\bar{\nu}+1)) \mathrm{Y}_{\mathrm{c}}$ ．Thus we immediately obtain for the ratio of multiplicities in the central region

$$
\begin{equation*}
\frac{\langle\mathrm{n}\rangle}{\mathrm{HA}}{ }^{\langle\mathrm{n}\rangle} \mathrm{HN}, \frac{\bar{\nu}}{2}+\frac{\bar{\nu}}{\bar{\nu}+1}, \tag{2}
\end{equation*}
$$

where the only dependence on the projectile $H$ is through the definition of $\bar{\nu}$ ．
The distribution of particles averaged over events produced from the ex－ citation of the nuclear partons is wedge－shaped．The ratio of distributions in the central region for hadron－nucleon to hadron－nucleus collisions is simply（ $\mathrm{y}_{\mathrm{A}} \equiv 0$ ）

$$
\begin{equation*}
\mathrm{R}_{\mathrm{A}}(\mathrm{y})=\frac{(\mathrm{dn} / \mathrm{dy})_{\mathrm{HA}}}{(\mathrm{dn} / \mathrm{dy})_{\mathrm{HN}}}=\bar{\nu} /_{1}-\frac{\mathrm{y}}{\mathrm{Y}_{\mathrm{c}}}+\left[1-\left(1-\frac{\mathrm{y}}{\mathrm{Y}_{\mathrm{c}}}\right)^{\bar{\nu}}\right] . \tag{3}
\end{equation*}
$$

Although Eqs．（2）and（3）are derived assuming a uniform plateau height in the central region，corrections to this shape tend to cancel in the ratio．

Thus far we have ignored the effects of the fragmentation regions．Eq．（1） predicts that the fast（e．g．，valence）partons interact only weakly ${ }^{8}$ and thus $\mathrm{R}_{\mathrm{A}}(\mathrm{y})=1$ in the projectile fragmentation region，and $\mathrm{R}_{\mathrm{A}}(\mathrm{y})=\bar{\nu}$ in the target fragmentation region．Let $\left\langle\mathrm{n}_{\text {frag }}\right\rangle_{\mathrm{H}}$ and $\left\langle\mathrm{n}_{\mathrm{frag}}\right\rangle_{\mathrm{N}}$ be the average number of particles produced in the projectile and nucleon fragmentation regions（i．e．， within $\Delta \mathrm{y}_{\mathrm{frag}} \sim 2$ units of the incident rapidity）．Then，instead of Eq。（2），we obtain

$$
\begin{equation*}
=\left(\frac{\bar{\nu}}{2}+\frac{\bar{\nu}}{\bar{\nu}+1}\right)-\left(\frac{\bar{\nu}}{2}-\frac{1}{\bar{\nu}+1}\right) \frac{<\mathrm{n}_{\mathrm{frag}^{>} \mathrm{H}}}{\left\langle\mathrm{n}_{\operatorname{tot}^{>} \mathrm{HN}}\right.}+\left(\frac{\bar{\nu}}{2}-\frac{\bar{\nu}}{\bar{\nu}+1}\right) \frac{<\mathrm{n}_{\mathrm{frag}^{>} \mathrm{N}}}{\left\langle\mathrm{n}_{\text {tot }} \mathrm{t}^{>} \mathrm{HN}\right.}, \tag{4}
\end{equation*}
$$

where $\left\langle\mathrm{n}_{\text {tot }}\right\rangle_{\mathrm{HN}}=\left\langle\mathrm{n}_{\text {central }}>+\left\langle\mathrm{n}_{\text {frag }}{ }^{>} \mathrm{N}+<\mathrm{n}_{\text {frag }}{ }^{>} \mathrm{H}\right.\right.$ is the total produced multiplicity for the $\mathrm{H}-\mathrm{N}$ collision. In practice the fragmentation correction terms are small, of order $(\Delta y)_{\text {frag }} / Y_{\text {total }} \sim O(1 / \log s)$ compared to $\bar{\nu} / 2$.

This result is compared with the data summary of Busza et al. ${ }^{9}$ in Fig. 2 for $\mathrm{p}_{\text {lab }}=200 \mathrm{GeV}$, taking $<\mathrm{n}_{\text {frag }}{ } \mathrm{H} /<\mathrm{n}_{\text {tot }}>\sim<\mathrm{n}_{\text {frag }}{ }^{\mathrm{N}} \mathrm{N} /<\mathrm{n}_{\text {tot }}>\sim$. 2 . It is in good agreement with the data for charged pion and proton collisions. In addition, the shapes of the observed multiplicity distributions are consistent with the predicted forms of Eq。(3) and Fig.1. The slight energy dependence predicted in Eq. (4) is also consistent with the trend of the data. ${ }^{10}$

We have analyzed the total nuclear cross section in this model and have found it to be consistent with the usual Glauber theory。 ${ }^{11}$ In this picture the incident hadron, which is represented by its Fock-space parton distribution, can interact elastically (diffractively) via elastic parton interactions in the central region and can continue to propagate and interact as a coherent hadron through the nuclear medium. ${ }^{12}$ Thus one obtains the usual multiple-scattering Glauber series. Nonetheless, the multiplicity density $\mathrm{dN} /$ dy produced from the incident projectile parton distribution is not increased by the repeated collisions. Because of the Glauber series, the cross section of course does not factorize: $\sigma_{\pi \mathrm{A}}^{\text {inel }} \sim \sigma_{\mathrm{pA}}^{\text {inel }}$ approach the geometric limit.

The model proposed here is consistent with energy and momentum conservation. In the equal velocity frame, the central particles produced in the projectile direction have a typical total energy of order $\bar{\nu}_{\mathrm{m}_{\mathrm{T}}},\left(\mathrm{m}_{\mathrm{T}}^{2}=\mathrm{m}^{2}+\left\langle\overrightarrow{\mathrm{k}}_{\perp}^{2}\right\rangle\right)$,
which can be compensated by a small loss of energy of the leading particles in the prejectile region, a correction of relative order $\overline{\nu_{m}} \mathrm{~T} / \sqrt{\mathrm{s}}$ 。

One may also use this picture to predict the multiplicity distributions in nucleus-nucleus collisions. ${ }^{12}$ For the central region one obtains

$$
\begin{equation*}
\frac{{ }^{\langle\mathrm{n}\rangle} \mathrm{A}_{1} \mathrm{~A}_{2}}{\langle\mathrm{n}\rangle \mathrm{NN}}=\bar{\nu}_{\mathrm{A}_{1}} / \mathrm{A}_{2}\left(\frac{\bar{\nu}_{\mathrm{A}_{2} / \mathrm{N}}}{\bar{\nu}_{\mathrm{A}_{2} / \mathrm{N}^{2}}+1}\right)+\bar{\nu}_{\mathrm{A}_{2}} / \mathrm{A}_{1}\left(\frac{\bar{\nu}_{\mathrm{A}_{1} / \mathrm{N}}}{\bar{\nu}_{\mathrm{A}_{1} / \mathrm{N}^{+1}}}\right) \tag{5}
\end{equation*}
$$

where

$$
\bar{\nu}_{\mathrm{A}_{1} / \mathrm{A}_{2}}=\frac{\mathrm{A}_{1} \sigma_{\mathrm{NA}_{2}}}{\sigma_{\mathrm{A}_{1} \mathrm{~A}_{2}}}
$$

is the average number of inelastically excited nucleons in $A_{1}$ in collision with a projectile $A_{2}$ 。 Each such excited $A_{1}$ nucleon interacts inelastically with $\bar{\nu}_{A_{2}} / \mathrm{N}$ nucleons in $A_{2}$ so that the average rapidity length of excited partons in $A_{1}$ is

$$
\left.\mid \bar{\nu}_{\mathrm{A}_{2} / \mathrm{N}} /^{\prime} \stackrel{\rightharpoonup}{\mathrm{A}}_{2} / \mathrm{N}+1\right] \mathrm{Y}_{\mathrm{c}}{ }^{\circ}
$$

Corresponding statements apply to $\bar{\nu}_{\mathrm{A}_{2}} / \mathrm{A}_{1}$ and $\bar{\nu}_{\mathrm{A}_{1}} / \mathrm{N}^{\circ}$ The above result predicts, for example, $\langle\mathrm{n}\rangle{ }_{\alpha \mathrm{A}_{2}} /\langle\mathrm{n}\rangle \mathrm{NA}_{2} \sim 3.8$ for $\mathrm{A}_{2}>100$, which is in agreement with cosmic ray data for alpha-particle collisions. ${ }^{13}$

Finally, we wish to point out the connection between our hypothesis of independently interacting and materializing nuclear parton chains and deep inelastic scattering measurements on nuclei. The latter directly probe the parton distributions within nuclei, and, according to our hypothesis, one should obtain

$$
\begin{equation*}
\nu \mathrm{W}_{2 \mathrm{~A}}\left(\mathrm{x}_{\mathrm{Bj}}\right) \cong \mathrm{A} \nu \mathrm{~W}_{2}\left(\mathrm{x}_{\mathrm{Bj}}\right) \tag{6}
\end{equation*}
$$

for all (including arbitrarily small) $x_{B j}=-q^{2} / 2 M_{N} \nu \lesssim 1$ once $q^{2}$ is in the Bjorken scaling region. ${ }^{14}$ For $\mathrm{x}_{\mathrm{Bj}}>1$, Fermi motion corrections can be included and computed using quark counting, ${ }^{15}$ but otherwise nuclear binding corrections to
(6) are considered negligible. Thus there is neither shadowing nor antishadowing ${ }^{16}$ of the partons of one nucleon by the partons of other nucleons. In general, we predict the absence of shadowing - independent of beam energy - for any reaction where the effective collision energy of the subprocess is large, $\mathrm{e}_{\mathrm{o}} \mathrm{g}_{\mathrm{o}}$, for the Drell-Yan Process pA $\rightarrow \ell^{+} \ell^{-} \mathrm{X}$ at large $\mathscr{M}_{\ell^{+} \ell^{-}}^{2}$, as well as for large $\mathrm{p}_{\mathrm{T}}$ hadronic reactions - ignoring multiple scattering effects. ${ }^{17}$ The absence of shadowing is also apparent in the ratio of distributions $R_{A}(x)=(d n / d x)_{H A} /$ $(\mathrm{dn} / \mathrm{dx})_{\mathrm{HN}}$ where x is the Feynman variable $\mathrm{k}_{\mathrm{c}_{4} \mathrm{~m}_{0}} / \mathrm{k}_{\mathrm{c}_{\mathrm{o}} \mathrm{m}_{0}}^{\mathrm{max}}$ 。At infinite energy $R_{A}(x)$ reduces in our model to a step function $R_{A}(x)=\bar{\nu} \theta(-x)+\theta(x)$ since the central region is confined to $\mathrm{x} \rightarrow 0$ 。 If we identify the nuclear parton distribution shape with the multiparticle distribution for $\mathrm{x}<0$, this again corresponds to the absence of shadowing: $(\mathrm{d} \sigma / \mathrm{dx})_{\mathrm{HA}}=\mathrm{A}(\mathrm{d} \sigma / \mathrm{dx})_{\mathrm{HN}^{\circ}}{ }^{18}$

In summary, we have found that the parton model can be consistent with both the strong absorption of nuclear cross sections and the relatively low multiplicity of hadron-nucleus collisions. Another problem which could be analyzed in this model is the propagation of virtual quark states and unstable resonances through the nuclear medium. ${ }^{19,20}$
