### ABSTRACT

We have set an upper limit on the  $\nu_\tau$  mass from a study of the four-pion invariant mass distribution in the decay  $\tau \rightarrow 3\pi^\pm\pi^0\nu_\tau$ . We obtain the limit  $m_{\nu_\tau} < 164 \text{ MeV}/c^2$  at the 95% confidence level.

Previous upper limits on the  $\nu_\tau$  mass of  $250 \text{ MeV}/c^2$  have been determined from a study of the electron spectrum<sup>1</sup> from the decay  $\tau \rightarrow e\nu_e\nu_\tau$  and from a study of the pion spectrum<sup>2</sup> from the decay  $\tau \rightarrow \pi\nu_\tau$ . In this Letter we report a new upper limit based on a study of the four-pion invariant mass spectrum in the decay  $\tau \rightarrow 3\pi^\pm\pi^0\nu_\tau$ . This decay mode is more sensitive to the  $\nu_\tau$  mass since the invariant mass of the four-pion state approaches the  $\tau$  mass.<sup>3</sup>

The data described in this Letter were taken with the Mark II detector at the  $e^+e^-$  storage ring PEP at a center of mass energy of 29 GeV. This detector has been described elsewhere.<sup>4</sup> We briefly describe the apparatus relevant to this analysis. The detector contains two charged particle tracking devices, a high precision drift chamber, known as the vertex chamber,<sup>5</sup> and a large drift chamber. The vertex chamber has seven layers of axial drift cells divided into an inner band of four layers at an average radius of 11 cm and an outer band of three layers at an average radius of 31 cm. The main drift chamber consists of 16 layers of sense wires at radii between 41 and 145 cm. Both tracking chambers are immersed in a 2.3 kG solenoidal magnetic field. For high momentum charged particles, the rms momentum resolution,  $\sigma_p/p$ , is approximately  $0.01p$ , where  $p$  is measured in GeV/c.

The central electromagnetic calorimetry is provided by eight rectangular lead-liquid-argon modules which surround the magnet coil. These modules are approximately 14 radiation lengths thick and provide an energy resolution of  $14\%/\sqrt{E}$ , where  $E$  is the energy measured in GeV.

The integrated luminosity of the data used in this analysis was  $158 \text{ pb}^{-1}$  and corresponds to a sample of 16300 produced  $\tau^+\tau^-$  pairs.

We selected events as  $\tau^+\tau^-$  candidates if they had a total detected energy

larger than 8 GeV and exactly four charged particles with zero total charge. Each event was divided into two hemispheres by a plane perpendicular to the thrust axis and was required to have three charged particles in one hemisphere recoiling against a single charged particle in the other. The acollinearity angle, defined as the angle between the total momenta of the particles in each hemisphere, had to be smaller than  $50^\circ$ . To select well measured events, we required each charged track to have signals in at least 14 layers of the two drift chambers, and to approach the vertex within 2 cm in the plane transverse to the beam direction and within 15 cm along the beam direction. We also required the total energy of the three charged particles to be less than 15 GeV. Events with a low-mass pair of tracks, one of which was identified as an electron, were rejected since this pair was most likely from a  $\pi^0$  Dalitz decay or from a photon which converted close to the interaction point. Electrons were identified<sup>6</sup> by the calorimeters when the electron energy was greater than 1 GeV and by the time of flight counters when the electron energy was less than 350 MeV.

At least two photons were required to accompany the  $\tau$  decay that contained three charged particles. Each photon was required to be detected well inside the fiducial volume of the calorimeter modules, to have a measured energy greater than 250 MeV, and to be separated by at least 20 cm in the calorimeter from all charged tracks with energy deposit in the liquid argon smaller than the minimum ionizing energy. To discriminate further against backgrounds due to charged particle interactions in the calorimeters, photons with measured energies less than 600 MeV were required to have a ratio of energy deposited in the rear layers to that deposited in the front layers of less than 1.5. Additional requirements were applied if the photon shared energy with other particles in one or two of the calorimeter coordinates.

A fit to the  $\pi^0$  mass was performed by adjusting the photon energies. To eliminate contributions from higher  $\pi^0$  multiplicity decays, we also required that no more than one  $\pi^0$  could be reconstructed from all combinations of the detected photons—that is, that at most one combination had  $\chi^2 < 10$ .

Figure 1 shows the  $\gamma\gamma$  invariant mass distributions after the above event selection requirements. There is a clear  $\pi^0$  signal with little background. There were 64 events in which the fit had a confidence level larger than 10% and these were retained. The fitted values for the photon energies were subsequently used in the calculation of the four-pion invariant mass.

The total energy of the  $3\pi^\pm\pi^0$  state was required to be greater than 8 GeV for  $m_{4\pi} < 1.5 \text{ GeV}/c^2$  and greater than 10 GeV for  $m_{4\pi} > 1.5 \text{ GeV}/c^2$ . This requirement loses 7% of the  $\tau$  events, while rejecting 50% of the hadronic background. Figure 2 shows the invariant mass distribution for the 60 events which survived all of the event selection criteria. There are no events between 2.0 and 2.5  $\text{GeV}/c^2$ . The background in Fig. 2 from hadronic events was determined from a Monte Carlo simulation to be 3% in the total sample, and  $(10 \pm 10)\%$  in the region  $m_{4\pi} > 1.5 \text{ GeV}/c^2$ . The resolution in invariant mass was determined from the Monte Carlo simulation as a function of  $m_{4\pi}$ . Its average value is  $(53 \pm 5) \text{ MeV}/c^2$  in the range  $m_{4\pi} > 1.5 \text{ GeV}/c^2$ .

The upper range of the  $m_{4\pi}$  spectrum,  $m_{4\pi} > 1.5 \text{ GeV}/c^2$ , was compared to the expected behavior<sup>7</sup> for different values of the  $\nu_\tau$  mass and different assumptions about the four-pion state. Only the upper part of the  $m_{4\pi}$  spectrum is sensitive to the  $\nu_\tau$  mass. The value of  $1.5 \text{ GeV}/c^2$  was chosen because it gives the best compromise between sufficient sensitivity and adequate statistics. A maximum likelihood method was applied to determine an upper limit from the 15 events in the  $m_{4\pi} > 1.5 \text{ GeV}/c^2$  region. The hadronic background was taken

to be distributed uniformly over the invariant mass range, as suggested by the Monte Carlo simulation.

If the  $\tau \rightarrow 3\pi^\pm \pi^0 \nu_\tau$  decay is assumed to have a pure phase space distribution, the upper limit on the  $\nu_\tau$  mass is  $155 \text{ MeV}/c^2$  at the 95% confidence level. If, as is more likely, the four pion state is assumed to be dominated by a  $\rho'$  resonance<sup>8</sup> of mass  $1570 \text{ MeV}/c^2$  and width  $510 \text{ MeV}/c^2$ , the limit is also  $155 \text{ MeV}/c^2$ . The results are not very sensitive to the various assumptions about the four-pion state since, in all cases, the  $m_{4\pi}$  spectrum close to the  $\tau$  mass is largely determined by the available phase space. The solid curve in Fig. 2 shows the calculated spectrum with the  $\rho'$  hypothesis and with  $m_{\nu_\tau} = 0$ . It is in good agreement with the data.

We checked the stability of the results by varying some of the parameters involved in the fit. If the experimental resolution in invariant mass is 20% worse than we have assumed, then the limit increases by 8%. If the fraction of background is increased from 10% to 30%, then the limit also becomes 8% worse. If the range of the invariant mass spectrum used in the fit is enlarged to  $m_{4\pi} > 1.3 \text{ GeV}/c^2$  instead of  $m_{4\pi} > 1.5 \text{ GeV}/c^2$ , nothing is added to the sensitivity and the limit does not change.

When we take into account the systematic uncertainties in our knowledge of the hadronic background, our experimental resolution, and the mass and width of the  $\rho'$  resonance, we obtain an upper limit on the mass of the  $\tau$  neutrino of  $164 \text{ MeV}/c^2$  at the 95% confidence level.

## ACKNOWLEDGEMENTS

We would like to thank P. Tsai for useful discussions. This work was supported in part by the Department of Energy, contracts DE-AC03-76SF00515 (SLAC), DE-AC03-76SF00098 (LBL) and DE-AC02-76ER03064 (Harvard).
