Abstract

After a very brief review of twentieth century elementary particle physics, prospects for the next century are discussed. First and most important are technological limits of opportunities; next, the future experimental program, and finally the status of the theory, in particular its limitations as well as its opportunities.

Invited talk given at the
International Conference on Fundamental Sciences:
Mathematics and Theoretical Physics
Singapore
13–17 March 2000

*Work supported by Department of Energy contract DE-AC03-76SF00515.

1 Preamble

It is a real pleasure to be back in Singapore and have the opportunity to address this meeting. About a decade ago, I gave a similar talk here, as a last-minute substitute for Leon Lederman [1]. Since that time I have for the most part exited theoretical physics and entered experimental physics. In particular I have been promoting new detector techniques for exploring the world of strong interactions. This led to my colleague Cyrus Taylor, a string theorist by training, and I leading a small test/experiment in the Fermilab Tevatron Collider. The results of this experiment were modest [2]. But the experience was in many ways extremely rewarding and enriching, and in other ways frustrating. However, as the new century begins, I have emerged from the experimental trenches and am entering the world of retirement. I now do have the opportunity to again take a look at the big picture, after a decade of time off. And the invitation to give this talk provided a most opportune way to organize my own thoughts and to try to express them.

2 The Big Picture

Twentieth century physics featured several great syntheses, The first was the extraordinary synthesis by Planck of thermodynamics with Maxwell electrodynamics, giving birth to quantum theory. It was quickly followed by the synthesis of classical mechanics with electrodynamics by Einstein, giving birth to special relativity. And in the 1920s, with the decisive synthesis of Newtonian mechanics with the “old” quantum mechanics by Heisenberg and Schrodinger, there also emerged quantum electrodynamics (or QED), the synthesis of Maxwell electrodynamics with quantum mechanics.

All this happened in less than three decades. Much of the remaining history for the century belongs to the experiments, which built upon these foundations and in particular drove the development of particle physics. Many particles were discovered. The strong and weak forces themselves needed to be discovered before there was any opportunity to understand their role. Eventually things became understood well enough that by the 1970s there was the possibility of a synthesis of weak and electromagnetic forces into a common structure: the $SU(2) \times U(1)$ electroweak component of the Standard Model. And the strong force is now successfully described by the generalization of QED called quantum chromodynamics (QCD), based on the exact $SU(3)$ color symmetry of quarks and their force carriers, the gluons.

All these forces (including gravitation) are described at short distances by the same class of fundamental theories, the so-called gauge theories. The force law at short distances is in all cases essentially inverse-square. Standard Model forces are proportional to a variety of conserved charges, while gravity couples to energy-momentum. So as we enter the twenty-first century, there is a strong anticipation that these four forces have a common origin and that further synthesis is on the way.

There are quite specific clues to build upon. One clue is the pattern of fundamental building blocks of matter: the quarks and leptons. They are exhibited explicitly as building blocks in Fig. 1. This is a construction which has technical meaning only when viewed beyond the Standard Model, when the $SU(3) \times SU(2) \times U(1)$ Standard Model symmetry group is embedded in the much larger symmetry group of ten-dimensional rotations, $SO(10)$. A clumsy, reducible representation of the Standard Model group becomes an elegant, single sixteen-dimensional fundamental spinor representation of $SO(10)$. In that context the 5-dimensional cube which is depicted in Fig. 1 has a definite mathematical meaning.

Figure 1: Building-blocks of the Standard Model. (The solid dots comprise the $SO(10)$ $\mathbf{16}$ for the two-component, left-handed fermion degrees of freedom; the open dots comprise the $\overline{\mathbf{16}}$ antiparticle representation.)

A second clue, pointing in the same direction, has to do with the fact that the coupling strengths or “charges” associated with the three kinds of Standard Model “gauge” forces vary slowly with distance scale. It happens that they converge (or very nearly converge) to a common value at a very high mass scale, 10^{15} GeV, give or take a factor 10, as shown in Fig. 2. It is at this scale that synthesis of these three forces can be expected to occur. This anticipated synthesis is known as Grand Unification.

Even one or two generations ago, it was the dream of every theorist to come to an understanding of the value of the pure number $1/137$ of QED, a number which characterizes the intrinsic strength of the electromagnetic force at the quantum level.

This is no longer the case. The 137 evolves to 128 through “vacuum polarization” effects; cf. Fig. 2. At this point, at a mass scale of about 100 GeV, the electroweak synthesis takes place. Thereafter it is the coupling strength of a mixture of photon and electroweak boson which, together with weak-boson and gluon coupling strengths, evolve from values of about 1/60, 1/30, and 1/10 respectively to the common value of about 1/40 at the grand-unification scale. So the 137 has been divided by a factor of about 3 1/2, and the question is now “Why 1/40?”

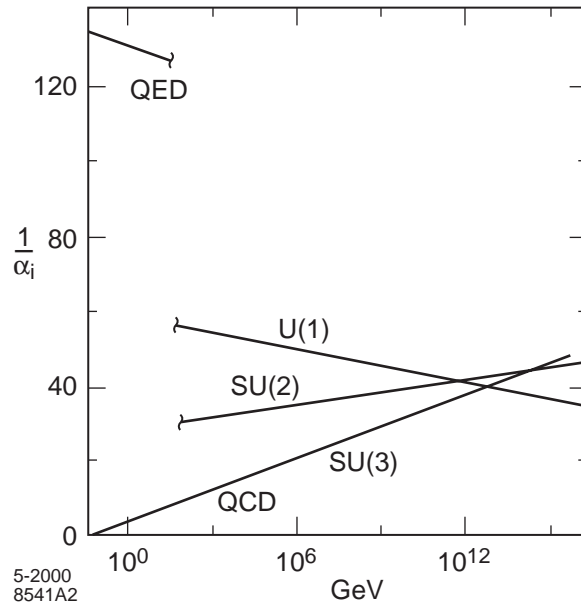

Figure 2: The “fine structure constants” of the basic forces as function of momentum scale. Note the discontinuity in the electromagnetic coupling strength at the electroweak scale, due to the replacement of $U(1)_{CM}$ with the Standard Model $U(1)_Y$.

There is another synthesis taking place at present, that of cosmology and particle physics. Twentieth century astronomy and astrophysics has its own rich history. But with the emergence of Big Bang cosmology in the last forty years, there has also emerged an increasingly strong interdependence of cosmology and particle physics. The high temperatures present during the early epochs of the Big Bang demand a good understanding of particle physics in any theoretical description, while the empirical evidence which constrains theories of the early history of the universe also constrains the theories of particle physics.

So there is now an increasingly strong interconnection of the largest distances with the smallest, and of the longest time scales with the shortest. This is illustrated in Fig. 3, which can truly be called the Big Picture. In that figure every effort has been

made to omit the superfluous. What is left is what I personally believe to be the key landmarks necessary to comprehend when moving on to the next syntheses.

Figure 3: The Big Picture: important values of distance (or momentum) scales versus time (as measured from the Big Bang).

Nothing of the Big Picture in Fig. 3 existed a century ago. That it exists now is a tribute to the extraordinary scientific progress made in that period. Progress in physical science has three components: technological, experimental, and theoretical. These are interconnected, but I believe that the order of importance is as stated. Without technological advances, experimental technique stagnates. And without the validations and unanticipated discoveries that comes from advances in experiment, the finest creations of theoretical physics languish as exercises in natural philosophy or in higher mathematics, and are of little worth as physical theory.

3 Technology

In particle physics the name of the game is energy. Throughout the twentieth century there has been exponential growth in the attainable center-of-mass energy available for particle collisions, beginning with a few electron-volts in early vacuum tubes and ending with the trillions of electron volts in the Fermilab Tevatron Collider [3]. On average this amounts to a doubling time of about 2-1/2 years.

This pace is unlikely to be equaled in the coming century. The slowing of the pace has already been apparent for the last decade or two. The new machines are big and

expensive, and take a long time to build and to fully exploit. But this does not mean an end to the field. There is plenty of room for further expansion of the possibilities, throughout the coming century.

Modern colliding beam machines are circular storage rings, within which some combination of counter-rotating beams of electrons, positrons, protons, and/or antiprotons collide with each other. The biggest electron-positron collider is the LEP ring at the CERN laboratory [4] in Geneva, Switzerland, 27 kilometers in circumference, and now running at a cms energy of about 200 GeV. This represents the limit of possibility for this kind of ring. The electrons and positrons emit so much synchrotron radiation, and the rate grows so rapidly with increasing energy, that it is impractical to contemplate similar machines at much higher energies. This is not the case for the heavier protons, where ten times that energy is attained in the Fermilab proton-antiproton collider already. And the Large Hadron Collider (LHC), under construction at CERN in the LEP tunnel itself [5], will increase this value sevenfold. Sooner or later, a similar synchrotron-radiation limit will be reached, however, especially given that superconducting magnets are needed to bend the protons, and that superconducting systems and intense beams of x-rays tend not to peacefully coexist. A rough estimate of where the ultimate limit for circular proton rings occurs puts the number at a few hundred TeV per beam. This is between one and two orders of magnitude larger than the LHC, and implies that at least one more very big collider is technically feasible [6], and perhaps affordable on a world scale sometime in the future.

Such a machine would be very big, probably over a thousand kilometers in circumference. It would require a lot of (underground) real estate, and for a long time it has seemed to me that this region of the planet, with Down Under so close at hand, is a natural focus when dreaming about this possibility. Given the premise that the twenty-first century will witness not only an economic but also scientific and cultural blossoming within Southeast Asia, such a project in this region might be an appropriate and locally beneficial way of entering this fundamental field of science. The time scale for even considering such an initiative is not at all immediate, but could be as short as two or three decades. And as we shall see, there are scientific considerations as well to deal with. What is done in the far future depends in an important way on what will be learned from the experiments performed in the nearer future.

When thinking about higher energy electron-positron collisions, the technique of choice is to accelerate the beams within straight-line, linear accelerators, as done in my home institution SLAC at Stanford, where collisions with 50 GeV electrons and positrons per beam have been attained [7]. Another factor of 10 to 20 can be contemplated using relatively straightforward extensions of existing techniques. The main issue is to do this in an energy-efficient, economical way. A great deal of study for the “Next Linear Collider” (NLC) is being carried out, with a large amount of international collaboration. And some kind of NLC is a leading candidate, perhaps the leading candidate, for the next large facility beyond the LHC needed to further push back the high energy frontier [8].

However there is a relatively new, competitive idea being studied as well, namely to collide muons and antimuons (the unstable, heavier second-generation copies of the electrons and positrons) with each other within circular storage rings (cf. Fig. 4). At first sight this idea looks crazy, but after careful scrutiny it becomes less crazy, albeit difficult and adventurous [9]. One physics advantage of muons over electrons and positrons is that resonant production of a Higgs boson is much larger and possibly observable. Another advantage is that muons do not emit so much synchrotron radiation. However many of them do decay en route to the collision point, and their decay products create a serious nuisance. An extremely intense source of primary muons is required.

Figure 4: A schematic of a muon collider. A very intense proton source creates a beam which is extracted and targeted. The pions and decay muons are focussed and collected. The large phase space occupied by the muon beam is diminished by “ionization cooling”. Then the muons are accelerated in a racetrack linac before being injected into the storage-ring collider.

But a general advantage of a muon collider facility is that there are many side-benefits. One can easily see that each component of the facility can—and should—support other physics programs. A very intense source of protons of tens of GeV is required, and this by itself is a good device for studying properties of the hadrons, including *e.g.* the rare decays of kaons. And the muons are accelerated in a recirculating linear accelerator which is a more powerful and sophisticated version of a facility, CE-BAF, now being used to study hadron structure via electron scattering [10]. Perhaps the most promising secondary application is utilization of the intense beams of neutrinos created by the decaying muons. Just in the last few years, with the emergence of the evidence for neutrino mass and mixing from non-accelerator experiments, there has been an escalating interest within the particle accelerator community in creating a “neutrino factory” using muon-collider technology. Such a program would provide useful neutrino physics as well as providing proof-of-principle evidence that the idea of creating intense, bright muon beams really can be made to work [9].

So while consideration of an NLC, with center-of mass energy of up to 1–2 TeV, will be high on the options list of future facilities beyond the LHC, the muon colliders, which might reach to a few TeV in the center of mass were all to go well, will also

be under consideration. It does have to be said that the muon-collider technology is new and untested, so that it is reasonable to expect that if that route is followed it will be considerably further into the century before one could contemplate high energy muon collisions being attained. In either case, the reason that such lepton colliders are competitive with the much higher energy pp colliders, such as the LHC, is the efficient conversion of all the energy in each event into interesting physics. The advantage of higher energy in pp colliders is mitigated by the complexity of the collisions and the relative rarity of the collisions which produce the highest-priority “new physics”.

In addition to the energy frontier, there will be many other frontiers remaining within particle physics. There are good reasons for producing interesting particles with the highest intensities possible. Accelerator facilities which specialize in production of a single kind of particle are already in abundance: we already see B factories, Z factories, K factories, and ϕ factories. And as mentioned above, we probably will see neutrino factories in the future. Once the Higgs sector, the prime target of experimental physics nowadays, is found, there will be an irresistible urge to create a Higgs factory as well, probably utilizing some kind of lepton-lepton collider. It is likely that the “factory” programs will have great longevity.

Another frontier is that of non-accelerator facilities, utilizing for example nature’s own particle beams, be they cosmic rays or neutrinos from the sun. When the ideas of grand unification emerged (Fig. 2), there also emerged the prediction of proton decay. This was a real turning point for the field of non-accelerator particle physics, because thereafter the large-scale investment in huge detectors became commonplace, and the level of sophistication relative to previous, traditional cosmic ray research escalated considerably. Even today the investment in non-accelerator particle physics is a relatively small fraction of the total, so that important measurements may be expected in the future to be approached on a scale larger than done at present. The recent advances in neutrino physics, especially in Japan with SuperKamiokande [11], bear witness to the value of making a large, sound investment in a good detector when the potential benefits warrant it.

But the non-accelerator experiments will forever be very difficult and fraught with more uncertainty than the more highly controllable accelerator experiments. So there will be strong motivation to push the high energy frontier well beyond what we have talked about so far. It is here that very difficult barriers appear.

If one wants to attain center-of-mass energies well beyond 1000 TeV, there seems to be very little choice but to do it with linear acceleration. If we ask to do this within a reasonable distance, say 100 km, this implies an average acceleration gradient of at least 10 GeV per meter, or 1 eV per Angstrom. High powered lasers can in principle provide forces of such a magnitude. But such forces, if present in matter, are strong enough to pull electrons out of metals, or in general destroy the orderly chemical structure of just about any material. There is a general rule, Lawson’s theorem, that states that free electromagnetic waves do not make a good accelerator, essentially because the electric vector is at right angles to the Poynting vector.

So a good accelerator will almost certainly have a material structure close to the beam, or perhaps a plasma within the beam. And this material structure might well be damaged or destroyed by the laser pulse or other source of the accelerating field every time the device is pulsed. I envisage this as the insertion of an accelerating structure into the beam, instead of the present practice of insertion of a beam into the accelerating structure.

The notion of an accelerator which is destroyed by the beam during every pulse is not necessarily a hopeless one, especially if the transverse dimensions of the machine are kept very small, not much larger than the beam itself. The small transverse dimensions are probably a necessity anyway on grounds of the energy budget. One cannot afford to fill a large cavity with a lot of energy, as presently done, especially when it does not directly contribute to the acceleration of the beam. So it could be that the accelerating structure is in the form of a sequence of structured tapes, or edges of structured rotating disks, which move through the beam region. The transverse scale might be anything from microns to millimeters.

And there is a new technology, nanotechnology, which although not viable now, might in the future evolve to the point that accurate, practical, and inexpensive (*i.e.* disposable!) acceleration microstructures might eventually be fabricated. Nevertheless, the trouble list associated with such a line of thinking is impressively formidable. A huge obstacle is that of maintaining the brightness of the beam, *i.e.* keeping the beam size small. The typical unit of periodicity (cell length) of such a “miniaturized” linear accelerator might be envisaged to be in the range of millimeters at most. So in a 100 km machine, there are at least 10^8 such cells. And the phase-space volume of the beam (emittance) cannot increase on average by much more than 1 part in 10^8 per cell or it will grow unacceptably large by the end of the machine. So the reproducibility of these extremely violent acceleration mechanisms must be maintained to a very high level of accuracy. I am sure this is only one of a number of similar problems.

There is in addition another great difficulty, which is motivation. It is a folk theorem in the trade that a project does best if there is strong physics motivation for it. The sense of urgency creates focus, drives the project forward, and encourages everyone to contribute that extra level of creative effort to make it successful. An R&D program on very high gradient linear accelerators will naturally be restricted to short prototypes for a long time, and therefore not be highly physics driven. And the primary physics demand is not only for high energy but also for an extremely high collision rate. Typically, for each factor of ten of energy increase, one needs to increase the luminosity, or collision rate, by a factor of order one hundred. But there are secondary physics topics which can be addressed. For example, were 10 GeV electron or proton beams to be produced, economically, on a tabletop in the basement of some university physics department, some physics uses for them might well be found. This is especially true for proton beams, where many physics applications do not require the relatively large intensities that electron-beam physics requires.

At present, there is actually considerable activity in the field of high gradient linear acceleration, not only theoretical but increasingly experimental [12]. It seems to me that there should be a high level of attention paid to this problem, even though it does not look to be immediately practical, and even though super-high gradients do not seem to be needed for at least a couple of generations of machines, in order to push the energy frontier forward. Sometime in the future the field will have to face up to this ultimate problem, and doing the homework now would seem to be a prudent strategy.

4 Experiments

In the realm of accelerator-based particle physics, the technology of particle detectors is highly advanced. In the future, as prognosticated in the previous section, refinements and extensions of the existing detector technologies can be expected to occur, especially with regard to rate capability, pattern recognition, resolution, and management of increasing data volume. But I at least do not perceive any need for a fundamental change of approach. The most difficult frontier is the providing of the higher energy collisions themselves, not in detection and analyzing the collision products.

Perhaps the most interesting experimental frontier is sociological. The size and complexity of experimental collaborations continues to grow. At present we see, at the LHC, collaboration sizes approaching two thousand, with participation of hundreds of collaborating institutions around the globe. And the time scale for construction and full exploitation of a single detector for a single experimental program rivals the full career length of the participating physicists. When I was here in Singapore the last time, I devoted quite a lot of time to this issue [1]. The social problems are still there. But there remains a large, enthusiastic young generation within the big detector collaborations, and I believe that the system, although very different from what it was two or three decades ago, still allows a highly creative and stimulating scientific environment.

Another singular feature of modern experimental particle physics is its professionalism. In the past two decades, the standards applied to all aspects of the experiments, especially with regard to the management and statistical analysis of the data, have soared. This is I think largely due to the size of the collaborations: they are large enough to contain experts in all the relevant subspecialties. I think these standards are well above what exist in other fields of science, and that participants in big experiments, even if they leave the field of particle physics at some point, are superbly prepared to apply that expertise in other scientific or technological applications.

Indeed, it must not be forgotten that experimental particle physics not only depends upon technological progress, but that it contributes to it. For example, it was the need for efficient communication and for transmission of very large volumes of information amongst the highly dispersed international community of collaboration

members that gave birth to the World Wide Web at CERN [13]. It is a perfect example of how research in basic science is not only an intellectual endeavor worthy of support by society for its own sake, but also an engine that drives economic progress in ways that create fundamental changes which are not programmable in advance.

It therefore seems to me that it is very important for Singapore and this region to not only consider the enhancement of its participation in basic science in the areas of theory, as represented in this meeting, but also to consider participation in experimental and accelerator physics. It is especially easy nowadays to enter the field via the large international experimental collaborations and thereby gain immediate access to the mainstream of the field. The benefits grow in proportion to the investment, and I would urge the creation of conditions that might allow participation of especially the younger generation in particle-physics experimentation.

5 Beyond the New Standard Model

We now turn to the theoretical situation. I believe, as do many others, that the most crucial problem we face has to do with understanding the mechanism by which the quarks, leptons, and electroweak force-carriers (the gauge bosons W and Z) get their mass. This problem is characterized by a mass scale at the edge of measurability at present, of order 100 to 1000 GeV. It was well defined already twenty years ago, and the efforts of many experiments, which have included the discovery and measurement of the properties of the W , Z , and the sixth, remarkably massive top quark, have simply sharpened the basic issues.

But the situation regarding the Standard Model has not remained static, thanks to the newest generation of neutrino experiments. They provide strong evidence that neutrinos also have mass and undergo “mixing”, similar to the way the three generations of quarks are mixed by the electroweak interactions. This is an extremely significant discovery, although not really a revolutionary one. It is in fact a very welcome one, one which replace the Old Standard Model by a New Standard Model. The 20 or so free parameters of the Old Standard Model are now increased by at least 7 (3 neutrino masses and 4 mixing angles) and perhaps 12 new parameters (masses for the 3 N 's discussed below plus two other mixing angles), depending upon what one chooses to include in the count. This by itself may not seem like progress. But the reason that neutrino mass is not all that unwelcome has to do with the Grand Unification perspective we mentioned earlier. In the Old Standard Model, there are 15 spin-1/2 building blocks per generation: the sixteenth degree of freedom N in Fig. 1 is not included. The natural GUT symmetry group to consider is $SU(5)$, for which the 15 building blocks fill two multiplets: a $\mathbf{5}$ and a $\overline{\mathbf{10}}$. Neutrino mass, in particular the very small neutrino mass observed, occurs in the $SO(10)$ extension when the extra degrees of freedom N_i (one for each generation of fermions) possess very large masses of order of the 10^{15} GeV GUT scale. The ordinary neutrinos mix with the N 's, and quantum mechanical level repulsion drives their masses to very

small values in a natural way. And with the N 's present, the pattern of the building blocks (Fig. 1) becomes simpler, as mentioned before, being described by a single 16-dimensional irreducible spinor representation of $SO(10)$. So the New Standard Model is to the Old Standard Model as $SO(10)$ is to $SU(5)$: a little bigger, and also a little prettier. And the transition from “Old” to “New” should be regarded as a very strong clue in dealing with the question of how to synthesize the strong and electroweak forces at the GUT scale.

Nevertheless, the problem of how the masses of quarks, leptons, W , Z , and neutrinos, are generated still must be faced. There are many ideas on how the problem of mass is to be solved. The most economical way requires only one extra particle to exist, the famous Higgs boson. In many ways, this simplest of scenarios, called the “desert” scenario, works the best. Consistency is maintained all the way to the GUT scale of 10^{15} GeV or so if and only if the mass of the Higgs boson lies in a narrow window: 160 ± 20 GeV. Nevertheless, theorists remain very disquieted by the “desert” scenario because there appears a quadratic divergence in the Higgs mass which must be subtracted away, and it seems very unnatural to set the physical Higgs mass to a small value at the electroweak scale of 100 GeV or so, rather than at the GUT scale of 10^{15} GeV.

However, this quadratic divergence problem bears great similarity to the problem of the small value of the cosmological constant. It too suffers from power-law divergences. And the cosmological constant problem cannot be solved with a straightforward appeal to supersymmetry, as is commonplace for the Higgs problem. So a serious “solution” to this “hierarchy” problem is to ignore it, acknowledging that its resolution will require a much deeper level of understanding, but recognizing that in the meantime renormalization (subtracting out the infinity) suffices to remove the problem from all known phenomenology.

But angst over the “hierarchy problem” has in the past 25 years spawned alternative approaches, the most important of which are phenomenological supersymmetry and “technicolor”. Both are characterized by the introduction of many new particles as well as new forces [14]. If either is correct, there will be an extraordinarily rich experimental program for the future.

The evidence from precision measurements of electroweak processes, especially at LEP, seems to favor a Higgs sector of relatively low mass, below 250 GeV [14]. This in turn is more in line with the supersymmetry option (“Minimal Supersymmetric Standard Model”, or MSSM), or the “desert” scenario than with technicolor, although nothing is strictly ruled out. The MSSM is especially rich in new particles and new parameters. Each known particle has its superpartner, differing in spin by 1/2, most of which having masses below a few TeV. There are about 100 extra parameters to be determined through experiment. The Higgs sector is bigger, and it is expected that at least one of the Higgs' lies below 130 GeV.

From the experimental point of view, these two alternatives, MSSM and “desert”, stand in stark contrast to one another. If MSSM is correct, then—once the energy scale has increased sufficiently to produce this cornucopia of new particles and

phenomena—it will be full employment for experimentalists (as it already has been for the MSSM theorists).

On the other hand, suppose none of that is found and only the single Higgs boson is seen, with a mass of 160 GeV as *predicted* by the “desert” scenario (cf. Fig. 5). It will be more difficult to motivate new, expensive facilities at higher energies if no clear landmarks for new phenomena exist.

Figure 5: Values of m_{Higgs} and momentum scale for which the Standard Model exists, *i.e.* where electroweak perturbation theory converges. The upper region is forbidden because the self-interactions of the Higgs particle become strong. The lower region is forbidden because the vacuum itself becomes unstable.

But the MSSM and “desert” scenarios are extreme cases. Yet another way of dealing with the hierarchy problem is simply not to have a hierarchy at all, but to have many new mass scales for new physics between the electroweak and GUT scales. In Fig. 6 is plotted versus mass m the number of (2-component) spin 1/2 fermions possessing mass no larger than m . At the GUT or Planck scale many theories, *e.g.* superstrings, end up with many hundreds of fermions. For example, three E(8) generations adds up to 744 fermions. At present energies we have ~ 48 . In both the “desert” scenario and the MSSM nothing much is supposed to happen across all those orders of magnitude. But perhaps there are “oases” of new physics all across the desert, which gradually release new degrees of freedom. The hierarchy problem becomes irrelevant. But, just like the “desert” scenario for experimentalists, the “oasis” scenario is a plague for theorists, because the vision of the GUT scale becomes obscured by everything which is in between, most of which is beyond experimental access.

Figure 6: Number of (Weyl) spin 1/2 particles (not including antiparticles) with mass less than m , versus m , for the “desert” scenario and the MSSM. At or beyond the GUT scale, many theories anticipate this number to be many hundreds to above a thousand.

The bottom line is simple. The next generation of experiments is sure to be a singularly important turning point for the field. The importance of the Higgs and new particle searches cannot be overrated.

6 Boundaries of Knowledge and Theories of Everything

For the last two decades, the subfield of theoretical particle physics with the most vitality, and with the most powerful intellectual force applied to it, is undeniably that of string theory. It is a most ambitious subfield, with the often claimed goal to be no less than a “theory of everything”, one which addresses the “unsolved” problem of synthesizing quantum mechanics with general relativity [15].

While I have no problem with what people do, I do have a problem with the rhetoric. In my opinion, a “theory of everything” is not a subfield of physical science, where a theory requires validation by experiment, but rather is a subfield of “natural philosophy”, which includes such fields as mathematics, philosophy, and religion, and which allows speculations and investigations unfettered by the constraints of experimentation and of the scientific method.

I also question the assertion that we presently have no quantum field theory of gravitation. It is true that there is no *closed*, internally consistent theory of quantum gravity valid at all distance scales, But such theories are hard to come by, and in

any case, are not very relevant in practice. But as an *open* theory, quantum gravity is arguably our *best* quantum field theory, not the worst. Feynman rules for interaction of spin-two gravitons have been written down, and the tree-diagrams (no closed loops) provide an accurate description of physical phenomena at all distance scales between cosmological scales, down to near the Planck scale of 10^{-33} cm. The divergent loop diagrams can be renormalized at the expense of an in-principle infinite number of counterterms appended to the Einstein-Hilbert action. However their effects are demonstrably small until one probes phenomena at the Planck scale of distances and energies [16].

One way of characterizing the success of a theory is in terms of bandwidth, defined as the number of powers of ten over which the theory is credible to a majority of theorists (not necessarily the same as the domain over which the theory has been experimentally tested). From this viewpoint, quantum gravity, when treated—as described above—as an effective field theory, has the largest bandwidth; it is credible over 60 orders of magnitude, from the cosmological to the Planck scale of distances. The runner-up is QCD, which loses credibility at the GUT scale. Above that scale QCD arguably gets synthesized into a new improved theory, in a way perhaps similar to the way QED gets synthesized at the electroweak scale. Indeed of the three theories, QED as formulated by Dirac and Heisenberg and renormalized by Feynman, Schwinger, and Tomonaga, has the worst bandwidth because it is already modified in an essential way at the electroweak scale.

In the old days QED was considered by Landau and others as an inconsistent (closed) theory, because the coupling constant α grows at short distances and eventually, at an incredibly short distance, blows up. This would in principle limit the bandwidth of QED to a mere 100 orders of magnitude or so. What a disaster! But in fact other physics intervenes. It is interesting that this inconsistency does not happen in QCD. The strong coupling constant only blows up in the infrared, where—with the help of experimental evidence—it is concluded that the theory remains consistent. Nevertheless, while QCD does enjoy the (unique) status of an experimentally relevant and logically consistent quantum field theory with infinite bandwidth, in practice it probably does not matter that this is the case, because almost certainly new physics will intervene at the GUT scale, if not sooner.

While quantum gravity may have splendid bandwidth, it still remains the case that at the Planck scale the effective field theory formalism totally falls apart. It is here of course that one finds the arena appropriate to the Theories of Everything. It is to be sure a valid and important arena. And it will be wonderful indeed if a successful theory can be put together at that scale. The trouble with doing so is that there is precious little guidance from experiment. What has always been typical for progress in physical science is a painful, slow progression, one step at a time, with guidance from experiment at most of the steps. Success with a theory of everything would be something very different and extraordinary—that of a theory found almost completely using arguments of symmetry and/or esthetics.

But no matter what, there are already many beneficial consequences of the theory-of-everything program. In its present state I see it as a theory of theories—the study of deep connections between different beautiful theories, some of which might conceivably be relevant to real physical phenomena. These connections will I am sure be covered in other talks. Certainly the theoretical phase-space of ideas has been greatly enlarged, for example in the considerations of supersymmetries, of extra space-time dimensions, of black hole phenomena, and even of more efficient ways for calculating Feynman diagrams. I would be very surprised if the future, improved theory does not contain some of the ideas spawned by the superstring revolution, even if superstrings have nothing to do with anything.

7 Macroscopic Quantum Gravity

Given the argument that quantum gravity is a good theory because it has large bandwidth, I now worry about whether I believe it. The issue is only whether the quantum-gravity phenomena not covered by perturbative Feynman-diagram calculations (which I consider safe territory) rest on solid foundations. This boils down to the question of black hole horizons and Hawking radiation, a subject which involves a nontrivial application of quantum gravity at distance scales large compared to the Planck scale. (The physics near a true gravitational singularity will also be nontrivial, but will be characterized presumably by physics at the Planck scale.) The potential problem that concerns me is that the black hole horizon (Schwarzschild radius) is a region characterized by very large complexity and very large bandwidth.

By this I mean the following. In Schwarzschild coordinates, place stationary observers a very small distance h above the horizon. Their job is to survey the local environment, as well as communicate with neighbors. As the horizon is approached, the spacing of such observers must decrease as \sqrt{h} ; otherwise they will not be able to send light signals to neighboring stations; the photons will fall into the black hole before getting there. So the number of such stations must be proportional to the black hole area, and depend inversely upon the height above the horizon. This result no doubt has something to do with black hole entropy, and is what I mean by increasing complexity as the horizon is approached.

The increase of bandwidth is related to the fact that, because of gravitational redshift, the surveyor's clock rate decreases toward zero as the horizon is approached, implying infrared sensitivity. The surveyor will see a divergent ratio of frequency of the light from his own Cesium clock, relative to light received from a distant Cesium-clock frequency standard. In addition the surveyor gets hot; he feels himself immersed in local Hawking radiation, with Hawking temperature which again diverges as the horizon is approached.

If our existing theoretical formalism has finite bandwidth, then the divergence in these quantities, which implies infinite bandwidth, may signal a sensitivity to new-physics phenomena at the horizon. Without an understanding of what the new

physics is, there is no *necessity* that something discontinuous happens to, say, the nature of the vacuum as the horizon is crossed, but only that there is a reasonable *possibility* that this might occur. I realize that this viewpoint cuts strongly against conventional wisdom, because freely falling observers are not supposed to “see” the infinite bandwidth phenomena that the Schwarzschild surveyors see. And it is also a necessity that the horizon which is considered here is not the event horizon used by Penrose and Hawking in their global analyses, but rather an apparent, or “redshift” horizon. (See Fig. 7 for a description of the distinction I have in mind.)

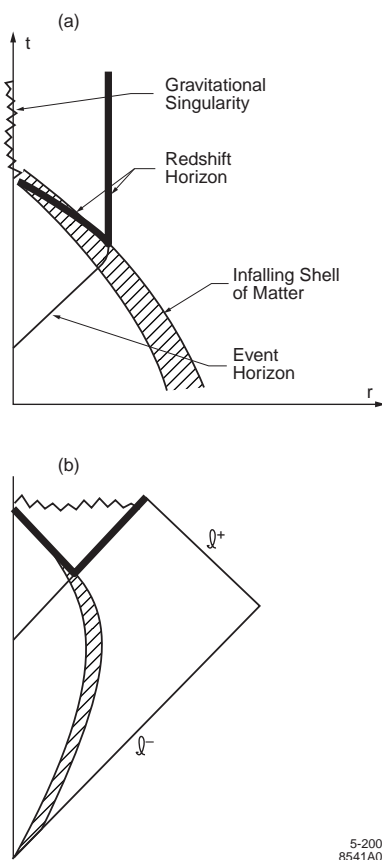

Figure 7: (a) Space-time history of a black hole created by a spherically symmetric shell of infalling matter, in Schwarzschild coordinates. Shown is the Schwarzschild radius and the Penrose-Hawking event horizon, within which no light ray can emerge to spatial infinity. Also shown is the “red-shift”, or “apparent” horizon which is pair-created by the infalling matter and which separates the interior region with $g_{00} < 0$ from the exterior region with $g_{00} > 0$. (b) The same picture, in a Penrose diagram.

While I am not yet sure of my ground and recognize that most experts do not share my doubts, I still find the Schwarzschild horizon a potential frontier, something akin to the frontiers posed by the Planck and cosmological distance scales. But maybe that is just my own shortcoming.

8 The Fate of QCD

As we have mentioned already, quantum chromodynamics (QCD), the theory of the strong force, is arguably the most comprehensive of the quantum field theories in use today, and in principle is a consistent closed theory with infinite bandwidth. In practice, there are two major branches of QCD, short-distance and long-distance. The former is dominated by a Feynman-diagram approach. It is basically perturbative in nature, although in practice large sets of diagrams need to be summed in order to attain the needed accuracy. And the short-distance limit has a host of applications and is of immediate relevance for all new-physics searches at the high energy frontier. For all these reasons there has been and will continue to be a large investment of effort in this area [17].

The large-distance limit, “soft QCD”, has to do with hadron structure and vacuum structure. The distance scale ranges from above 10^{-13} cm to a little below 10^{-14} cm, essentially the size scale associated with ordinary hadrons. Here perturbation theory cannot be reliably used, and therefore the theory is much more challenging. Many open questions remain, the most prominent being a full description of the phenomenon of quark confinement.

The vacuum structure of QCD is especially rich. At moderate distances there is the challenge of understanding the role of instantons. At large distances, there exists a “chiral condensate”, emergent from the spontaneous breaking of the approximate strong-interaction chiral symmetry. And the QCD phase diagram needs explication; at present there is a lot of progress in the theory [18]. And the exploration of heavy ion collisions at CERN and soon at the RHIC ion-ion collider at Brookhaven [19] makes the experimental situation also a dynamic one.

At short distances hadrons are described in terms of the pointlike quark-gluon, “parton” degrees of freedom. Much is known about the momentum spectrum of these partons, viewed in reference frames where the parent hadron has very high momentum. But precious little is understood about the correlations between the partons. For example, how they are distributed in the transverse plane is still a serious issue, and even the multiplicity distribution of the partons is not established. And the nature of the low-momentum tail of the distribution, the “wee” partons of Feynman, remains an active and unresolved issue.

Ordinary collisions at the very high energies of the LHC are another frontier. So many “wee” partons participate simultaneously in the typical central proton-proton collision that the complexity of the dynamics, *e.g.* the number of relevant constituent collisions per proton-proton collision, exceeds what will be dealt with in gold-gold

collisions at RHIC. Diffractive processes comprise another difficult and unresolved subfield, one which increases in prominence with increasing energy. It is a “shadowy” topic which probably involves large-distance QCD concepts in an essential way[20].

Even the venerable subject of hadron spectroscopy ought to have a rich future. A modern “electronic bubble chamber”, built to exceed the classic bubble chamber’s acceptance and resolution, could improve the statistics and data quality of all the old resonance-physics topics by a millionfold. Many anticipated resonant states of hadrons, especially those made primarily of gluons, remain to be discovered and carefully studied.

I prefer to label this whole subfield “Hadron Physics”, in analogy to atomic, molecular, and nuclear physics. The goals of those subfields are quite analogous to the goals of hadron physics—namely to study the internal structure of their building blocks, as well as to study their “vacua”, namely the extensive, condensed-matter structures built from those constituents.

These subfields, especially atomic and nuclear physics, used to be within the mainstream of elementary particle physics. As the energy scale of interest to particle physics increased, each evolved into a distinct discipline. And I think this is already happening to hadron physics. Relatively little attention is paid nowadays by mainstream particle physicists to the subfield of hadron physics. And a great deal of the subject matter is now appropriated by the nuclear physics community, even though what they are doing can hardly be called nuclear physics.

While this evolution is basically a natural one, there is a new problem which was not faced in the previous examples. Much of the experimental program of hadron physics needs to be done via high energy collisions, within the facilities built and exploited by particle physicists. It is not easy for hadron-physics initiatives to be recognized and to receive the necessary priority rating, whether from laboratory managements, program committees, funding agencies, or the existing peer review system, when a program dedicated to hadron structure is put in direct competition with major high-energy physics initiatives. I believe that in order for such hadron-physics initiatives to be viable, there must be institutional changes at all these levels, which recognize the complementary nature of hadron-physics research, and which provide a certain degree of guaranteed access to the high-energy facilities in return for an appropriate contribution to the operating costs of the facilities [21].

9 Remarks

In summary, elementary particle physics in the next century should continue to be full of progress and full of vitality. While there is a slowing of the pace, it is still the case that within the next decade we should already witness a major turning point, namely a much better understanding of the problem of mass and of the mechanism of electroweak symmetry breaking. The way in which that problem is answered will have much to do in shaping the nature of the experimental program beyond.

The vitality of theory nowadays is focused on the superstring ideas, which continue to generate new ways of looking at the fundamental problem of going beyond the standard model. The only problem with this activity is its remoteness from data. This in itself causes me no problem. But if it leads to an indifference of theorists toward the data-driven side of the field, then I will have a problem.

When new data appears at a relatively slow rate, ideas and interpretations tend to ossify, and it sometimes becomes harder not only to think in new ways, but also to maintain a diversity of approach, which is always an essential element of the scientific endeavor. The existence of the Standard Model does not imply the existence of a standardized anticipation of the future. The only thing that deserves institutionalization is doubt. This problem of maintaining diversity of approach afflicts both experiment and theory, and if I have any concern about how the field is developing, it is about this point I worry the most.

In this respect, the second-tier initiatives such as the “factories”, and new generations of non-accelerator facilities are important to encourage. And I would add QCD and hadron-physics initiatives to this list as well. There is very much to do, most of which is relatively accessible provided the resources are made available. And last but not least, the long range problem of reaching extremely high energies should not be neglected, implying good support for advanced accelerator R&D.

10 Acknowledgments

It is a pleasure to thank the organizers of this conference for the excellent program and fine hospitality extended to us all. I also thank Pisin Chen, Leon Lederman, Chris Quigg, and Leonard Susskind for critical comments and advice.
