ABSTRACT

Lattice QCD predicts a phase transition between hadronic matter and a system of deconfined quarks and gluons (the Quark Gluon Plasma) at high energy densities. Recent results from the Brookhaven Relativistic Heavy Ion Collider (RHIC) dedicated to the study of QCD at extreme densities will be discussed and compared to measurements obtained at the CERN Super Proton Synchrotron (SPS).
1 Introduction

Quantum Chromo Dynamics (QCD) provides, as part of the standard model, a very successful description of strong interaction processes involving large momentum transfer. However, from first principles several important aspects of QCD are still poorly understood. Examples are color confinement, chiral symmetry restoration and the structure of the vacuum. Better understanding of these concepts can be obtained if we are able to study quarks and gluons in a deconfined state, the so called Quark Gluon Plasma (QGP).

Such a deconfined state might be created in the laboratory in heavy-ion collisions at the highest energies. Theoretical guidance for this comes from Lattice QCD calculations. Lattice QCD predicts that at an energy density $\epsilon \approx 1 \text{GeV}/\text{fm}^3$, corresponding to a temperature of about 170 MeV, the system undergoes a phase transition from nuclear matter to a deconfined system of quarks and gluons.

Figure 1a shows the energy density divided by the fourth power of the temperature, $T$, versus the temperature from a lattice calculation [1]. This figure shows that in between 150-200 MeV, the energy density increases rapidly which is indicative of a phase transition where at high temperature the quarks and gluons become the relevant degrees of freedom. The figure also indicates where according to our current understanding the different heavy-ion machines are located on this diagram. These calculations are done with zero baryon chemical potential, $\mu_B$, reflecting the conditions of the early universe. Small values of the chemical potential are obtained at RHIC collider energies whereas at lower energies, e.g. AGS and SPS, the value of $\mu_B$ is large. In Fig. 1b the relation between the transition temper-
ature and the chemical potential from recent lattice calculations [2] is shown. The
calculation indicates that the transition temperature decreases with increasing $\mu_B$
and furthermore that at low $\mu_B$ the transition from the hadronic phase to the QGP
is a rapid crossover (dotted line) while at large $\mu_B$ a first order transition should
take place (full line).

2 The Relativistic Heavy Ion Collider (RHIC)

Heavy-ion physics entered a new era with the advent of the Relativistic Heavy Ion
Collider (RHIC) at Brookhaven National Laboratory. RHIC is a versatile collider
providing collisions with different ion species (ranging from protons to gold) at a
wide range of center of mass energies $\sqrt{s_{NN}}$. In the three years of operation collision
were provided for Au+Au at 19.7, 130 and 200 GeV, p+p at 200 GeV and d+Au
at 200 GeV. Note that the top center of mass energy for p+p is 500 GeV at RHIC.
For details on the detectors, see [3].

3 Event Characterization

Heavy-ions are extended objects and the system created in a head-on collision is
different from that in a peripheral collision. Therefore, collisions are categorized
by their centrality. Theoretically the centrality is characterized by the impact pa-
rameter $b$ which, however, is not a direct observable. Experimentally, the collision
centrality can be inferred from the measured particle multiplicities if one assumes
that this multiplicity is a monotonic function of $b$. Another way to determine the
event centrality is to measure the energy carried by the spectator nucleons (which
do not participate in the reaction) with Zero Degree Calorimetry (ZDC). A large
(small) signal in the ZDCs thus indicates a peripheral (central) collision.

Two other measures of the centrality which are often used are the number
of wounded nucleons and the equivalent number of binary collisions. These numbers
are related to the impact parameter $b$ using a realistic description of the nuclear
geometry in a Glauber calculation, see Fig. 2. Phenomenologically it is found that
soft particle production scales with the number of participating nucleons whereas
hard processes scale with the number of binary collisions.

4 Low-$p_t$ Observables

Examples of global observables which provide important information about the cre-
atated system are the particle multiplicity and the transverse energy. Figure 3 shows
the transverse energy versus the collision centrality as measured at $\sqrt{s_{NN}} = 130$ GeV by the PHENIX collaboration [4]. This measurement allows for an estimate of the energy density as proposed by Bjorken [5]

$$\epsilon = \frac{1}{\pi R^2} \frac{1}{c\tau_0} \frac{dE_T}{dy},$$

were $R$ is the nuclear radius and $\tau_0$ is the effective thermalization time (0.2-1.0 fm/c). From the measured $\langle dE_T/d\eta \rangle = 503 \pm 2$ GeV it follows that $\epsilon$ is about 5 GeV/fm$^3$ at RHIC. This is much larger than the critical energy density of 1 GeV/fm$^3$ from Lattice QCD (see Fig. 1).

Figure 4 shows the charged particle multiplicity distributions versus the pseudorapidity $\eta$ measured by PHOBOS at three different energies [6]. The gross features of the particle multiplicity distributions are described by a similar behavior of the tails of the multiplicity distributions (limiting fragmentation) and a plateau at mid-rapidity consistent with a boost invariant region of $\Delta y \approx 1$. Notice that in total about 5000 charged particles are produced in the most central Au+Au collisions at the top RHIC energy.

4.1 Particle Yields

The integrated yield of the various particle species provides information about the production mechanism and the subsequent inelastic collisions. A very successful description of the relative particle yields is given by the thermal model. In Fig. 5 the particle yield ratios measured at RHIC are plotted and compared to values from a thermal model fit [8]. The lines from the thermal model show that all particles
Figure 4: Multiplicity versus pseudo-rapidity for 19.6, 130 and 200 GeV measured by PHOBOS [6].

Figure 5: Particle yield ratios at RHIC compared with a thermal model [8].

ratios are consistent with a single temperature and single chemical potential in a thermal description. The temperature obtained this way, 176 MeV, is called the chemical freeze-out temperature and the measured value is very close to the phase boundary value in lattice calculations (see Fig. 1b). Figure 6a shows the relative particle ratios of pions, kaons and protons and their anti-particles versus rapidity [7]. For the heavier particles the ratio drops rapidly for $y > 1$. Figure 6b shows the ratio of $K^-/K^+$ versus $\bar{p}/p$ for AGS to RHIC energies. The decreasing ratio of $\bar{p}/p$ as a function of rapidity can thus be understood from the changing baryon chemical potential at a constant chemical freeze-out temperature.
4.2 Spectra

The particle spectra provide much more information than just the integrated particle yields. The particle yield as a function of transverse momentum reveal the dynamics of the collision, characterized by the temperature and transverse flow velocity of the system at kinetic freeze-out. Kinetic freeze-out corresponds to the final stage of the collision when the system becomes so dilute that all interactions between the particles cease to exist so that the momentum distributions do not change anymore. Figure 7a and b show the transverse momentum distributions at $\sqrt{s} = 17$ GeV from NA49 [9]. The lines are a fit to the particle spectra with a hydrodynamically inspired model (blast wave). The fit describes all the particle spectra rather well which shows that all these spectra can be characterized by the two parameters of the model: a single kinetic freeze-out temperature and a common transverse flow.
velocity. Figure 7c shows the combined pion, kaon and proton $p_t$-spectra from the four RHIC experiments. Also at these energies it follows from a common fit to all the spectra that the system seems to freeze-out with at a similar temperature and with a transverse flow velocity as observed at SPS energies.

4.3 Azimuthal Correlations with the Reaction Plane

The nuclear overlap region in non-central collisions has an almond like shape with its longer axis perpendicular to the reaction plane (the plane defined by the beam axis and the impact parameter). This particular shape leads to a pressure gradient which is different in and out of the reaction plane which, in turn leads to azimuthally asymmetric particle emission. The asymmetry can be described by:

$$\frac{E}{d^3N} \frac{d^2N}{dp} = \frac{1}{2\pi} \frac{d^2N}{dp} dy \left( 1 + \sum_{n=1}^{\infty} 2v_n \cos(n(\phi)) \right)$$ and $v_2 = \langle \cos(2\phi) \rangle$

where $\phi$ is the azimuthal angle with respect to the reaction plane and the coefficient of the second harmonic, $v_2$, is called elliptic flow. The magnitude of $v_2$ and its $p_t$ dependence allows for the extraction of the kinetic freeze-out temperature and transverse flow velocity as function of emission angle.

Figure 8 shows the measurement of $v_2$ versus $p_t$ for pions and protons plus antiprotons. Due to transverse flow the $p_t$ dependence of $v_2$ depends on the particle mass as is evident from Fig. 8. Also shown in this figure are hydrodynamical model calculations using two different equations of state [15] corresponding a hadron gas and a QGP. It is seen that the QGP EOS shows the best agreement with the data. In Fig. 9 RHIC data on $v_2(p_t)$ [16, 17, 18, 19] for various particles are compared.
to a hydrodynamical inspired blast wave fit. The agreement of the data with the blast wave fit shows that all the $v_2(p_t)$ for all particles can be described in terms of a single temperature and a $\phi$-dependent transverse flow velocity. Furthermore, the magnitude and $p_t$ dependence of the elliptic flow for the various particles suggest strong *partonic* interactions in an early stage of the collision and, perhaps, early thermalization of the system.

5 High-$p_t$ observables

In heavy-ion collisions at RHIC, jets with transverse energies above 40 GeV are produced in abundance, providing a detailed probe of the created system. However the abundant soft particle production in heavy-ion collisions tends to obscure the characteristic jet structures. At sufficient high-$p_t$ the contribution from the tails of the soft particle production becomes negligible and jets can be identified by their leading particles. It was proposed that a leading particle traversing a dense system would lose energy by induced gluon radiation (so called jet-quenching [20]). The amount of energy loss is in this picture directly related to the parton density (mainly gluons at RHIC) of the created system. Currently there are three observables sensitive to this energy loss as discussed in the next two subsections.

5.1 Single Inclusive Particle Yields

As mentioned above, the single inclusive particle yield at sufficiently high-$p_t$ is dominated by the leading particles from jets. Figure 10a shows the $\pi_0$ spectra as measured in p+p at $\sqrt{s} = 200$ GeV. In the same figure also two NLO QCD calculations are shown. The ratio of the data to the theory shows that in p+p the $\pi_0$ spectrum is well described. In Fig. 10e the charged hadron spectra measured in Au+Au at $\sqrt{s_{NN}} = 200$ GeV and the p+p reference spectra at the same energy are shown. One of the observables suggested for measuring energy loss is the so called nuclear modification factor:

$$R_{AA}(p_t) = \frac{d^2\sigma_{AA}/dydp_t}{\langle N_{\text{binary}} \rangle d^2\sigma_{pp}/dydp_t}$$

where $d^2\sigma_{pp}/dydp_t$ is the inclusive cross section measured in p+p collisions and $\langle N_{\text{binary}} \rangle$ accounts for the geometrical scaling from p+p to nuclear collisions. In the case that a Au+Au collision is an incoherent superposition of p+p collisions this ratio $R_{AA}$ would be unity. Energy loss and shadowing would reduce this ratio below unity while anti-shadowing and the Cronin effect would lead to a value above unity. Figure 11b,c shows this ratio for charged particles and $\pi_0$'s in central Au+Au

225
collisions at mid-rapidity. The ratio is well below one and at high-$p_t$ the suppression is a factor 5. At intermediate $p_t$ the charged particles and $\pi_0$'s are both suppressed; however the magnitude differs by a factor of two. In Figure 11d $R_{AA}$ is plotted at more forward rapidities showing that the suppression also persists there.

To discriminate between energy loss and shadowing, d+Au collisions were measured. If the suppression is due to shadowing it should also be observed in the d-Au system. Figure 11a shows the d+Au spectra versus centrality and Fig. 11b,c the nuclear modification factor for charged particles and $\pi_0$'s respectively. It is clear that in d+Au interactions no suppression is observed. In fact, to the contrary, a small enhancement is seen consistent with the Cronin effect. From this observation it follows that the observed suppression in Au+Au collisions is due to final state interactions. The magnitude of the observed suppression at the top RHIC energy indicates, in the jet quenching picture, densities which are a factor 30 higher than in nuclear matter.

5.2 Azimuthal Correlations

In heavy-ion collisions, azimuthal correlations between particles can be used to study the effect of jet quenching in greater detail. The azimuthal correlations of two high-$p_t$ particles from jets are expected to show a narrow near side correlation and a
broader away side correlation. However, in the case of strong jet quenching the away side jet would suffer significant energy loss and would be suppressed. Recently, CERES measured such a correlation function at the top SPS energy. In Fig. 12a the nearside correlation (at $\Delta \phi = 0$) shows a narrow peak consistent with the correlation observed in jets. The away side correlation peak is observed in more peripheral collisions but disappears for more central collisions, see Fig. 12b. Figure 12c shows that the width ($\sigma$) of the near side correlation peak stays constant as a function of centrality, but that the away side peak broadens for more central collisions. The total integrated yield is the same in the near and away side peak (Fig. 12d). Therefore, the disappearance of the away side peak at the top SPS energy is interpreted as being due to initial state broadening [26].

The azimuthal correlations of high-$p_t$ particles (trigger particle $4 < p_t < 6$ GeV/$c$, associated particle $2$ GeV/$c < p_t < p_{t,\text{trig}}$) measured in p+p collisions at RHIC are shown as the histogram in Figure 13b. The near side and away side peaks are clearly visible. The correlation function observed in central Au+Au collisions

Figure 11: $d+\text{AU}$ and $\text{Au+Au}$ measurements from PHOBOS [24], STAR [22], PHENIX [23] and BRAHMS [25].
Figure 12: CERES [26] (SPS), azimuthal correlations.

Figure 13: a) back to back correlations [27] and b) elliptic flow parameter [17] at intermediate-$p_T$.

(stars in Fig. 13b) shows a similar near side peak while the away side peak has disappeared.

To investigate if this is due to initial state effects, the same analysis was done for d+Au collisions. In Fig. 13a the near and away side peaks are shown for minimum bias and central d+Au collisions compared to p+p. The away side correlation in d+Au is clearly observed even for the most central collisions. Comparing the away side correlation in p+p, d+Au and Au+Au, Fig. 13b, shows that the suppression only occurs in Au+Au collisions and therefore is a final state effect as expected from jet quenching.

The energy loss depends on the distance traversed through the dense medium by the partons. In a non-central collision the distance will depend on the azimuthal angle with respect to the reaction plane (see low-$p_T$ section). Because the hard scattering producing the di-jet has no correlation with the reaction
plane, an observed asymmetry in the high-$p_t$ particle emission will be due to final state interactions (such as the jet quenching mechanism). In Fig. 13b the observed elliptic flow signal as a function of $p_t$ is shown for charged particles, kaons and lamdas. It is clear from this figure that the observed asymmetry is very large up to the highest $p_t$ measured. Like the nuclear suppression factor $R_{AA}$, the elliptic flow at intermediate-$p_t$ depends on the particle species. This could be due to an interplay between the soft hydrodynamical behavior and the jet quenching, which would cause a mass dependence. However, more recently this has been interpreted as a possible sign of particle production at intermediate $p_t$ by parton coalescence. In that case it is not the mass of the particle which is responsible for the splitting but rather the number of constituent quarks (splitting between mesons and baryons). A definitive test will be the measurement of elliptic flow of the $\phi$-meson because in the coalescence interpretation it should have an elliptic flow similar to the pions but in the hydrodynamical interpretation is would have an elliptic flow value similar to the proton.

6 Conclusions

The first three years of RHIC operation have provides us with a wealth of interesting data. We have seen that:

- Particle yields indicate a chemical freeze-out of the system near the phase boundary;

- Identified particle spectra are consistent with boosted thermal distributions and identified particle elliptic flow shows remarkable agreement with ideal hydrodynamical calculations based on a QGP equation of state;

- The particle yield at high-$p_t$ is suppressed compared to proton-proton reference data. The fact that this suppression does not occur in $d+Au$ collisions shows that it is a final state effect, consistent with parton energy loss in dense matter (jet quenching);

- The suppression at intermediate-$p_t$ shows a particle dependence which could be explained by particles being produced at intermediate-$p_t$ by means of parton coalescence;

- The elliptic flow at intermediate-$p_t$ is large and also shows a particle dependence. Like above, this is consistent with energy loss in dense matter and particle production via parton coalescence;
In the most central events the high-$p_t$ back to back correlations are consistent with zero. Such disappearance of the away side jets is expected in the case of very strong energy loss in a dense medium.

All these observations, taken together, are consistent with the creation of a very dense and strongly interacting system in heavy-ion collisions at RHIC energies. While all these observations are consistent with the creation of a QGP, more detailed knowledge of QCD at high densities and temperatures is required. This poses a formidable challenge for theory but will be crucial for the detailed interpretation of the present and future data taken at RHIC and LHC.
