ABSTRACT

In the decay of the τ lepton into a spin one meson and a neutrino, the meson state with helicity opposite its charge is forbidden by angular momentum conservation if the decay is mediated by the conventional V - A current. The laboratory momentum distribution of pions in the decay chain \( \tau \rightarrow \rho \nu, \rho \rightarrow \pi \pi \) reflects the polarization of the \( \rho \) meson and provides an experimental check of the nature of the decay current. This method requires the identification of the decay mode \( \rho \nu \) but does not depend on finding the \( \tau \) laboratory direction.

The nature of the current mediating the heavy lepton [1] decay has been convincingly established for the leptonic modes for which the V - A theory fits the electron and muon spectra [2,3]. Of the identified semileptonic modes the \( \pi \nu \) decay distributions are sensitive to the coupling structure only for polarized \( \tau \) which have not been obtained so far. However, the decays of the \( \tau \) into a spin one meson and a neutrino offer the possibility of observing effects reflecting the nature of the current. Weak decays involving vector mesons have

(Submitted to Physical Review D)
been discussed previously in another context [4]. As shown in
Fig. 1, if the \( \tau \) neutrino is massless and the decay proceeds via
the \( V - A \) current, the helicity state of the meson opposite the sign
of its charge is forbidden by angular momentum conservation. This
polarization of the meson is independent of the polarization state
of the \( \tau \), and is present in the observed events in existing
electron-positron colliding beam rings. Further, for the decay
\( \tau \rightarrow \rho \nu \) [5], the decay of the \( \rho \) into two pions is a good analyzer of
the \( \rho \) polarization.

While the measurement of the \( \rho \) density matrix seems too
ambitious experimentally [6], noticeable effects persist in the
laboratory energy distribution of pions and these can be readily
measured.

Many features of the \( \tau \rightarrow \rho \nu \) process have been discussed
before [7,8]. The angular distribution of the \( \rho \) in the \( \tau \) rest frame
is given by

\[
\frac{dN}{d\Omega_\rho} = \frac{M_{\rho}^2}{4\pi(M_{\tau}^2 + 2M_{\rho}^2)} \cdot (1 + \eta \cdot \hat{\mathbf{s}})/|\vec{k}| )
\]

(1)

for helicities \( \lambda = \pm 1 \), and by

\[
\frac{dN}{d\Omega_\rho} = \frac{M_{\tau}^2}{4\pi(M_{\tau}^2 + 2M_{\rho}^2)} \cdot (1 - \eta \cdot \hat{\mathbf{s}})/|\vec{k}| )
\]

(2)

for helicity \( \lambda = 0 \). Here, \( \eta \) is the charge of the \( \tau \), \( \hat{\mathbf{s}} \) is a unit
vector directed along its spin and \( \vec{k} \) is the rest-frame \( \rho \) momentum.
When both orientations of the $\tau$ spin are equally probable, the $\rho$ distribution becomes isotropic, but the state with $\lambda = -1$ is nevertheless forbidden, while the zero-helicity state is favoured in the ratio $M_\tau^2/(2M_\rho^2)$ with respect to the $\lambda = 1$ state. Thus, in the $\rho$ rest frame, the angular distribution of pions with respect to the line of flight of the $\rho$ in the $\tau$ rest frame is given by

$$\frac{dN}{d\Omega} = \frac{3}{4\pi(M_\tau^2 + 2M_\rho^2)} \left(\frac{M_\rho^2}{M_\tau^2} + \frac{M_\tau^2}{M_\rho^2} \cos^2 \theta\right)$$

and appears in Figure 2.

The marked anisotropy in Eq.(3) is due to both the angular momentum selection rule and the relative probability that the $V - A$ interaction ascribes to the allowed helicity states of the $\rho$. The laboratory energy distribution of pions is obtained by applying the appropriate Lorentz boosts. We evaluated it at electron-positron energies of 2.5 and 14.5 GeV/beam and compared it in Figure 3 with that obtained neglecting the $\rho$ polarization. The $\rho$ resonance was described by a Breit-Wigner function around the mass $M_\rho = 0.776$ GeV with width $\Gamma_\rho = 0.155$ GeV. Radiative effects have been neglected.

The difference between the energy distributions in Figures 3a and 3b can be expressed by the second moment (variance) of each distribution. At 2.5 GeV the energy distribution has a variance of 0.034 while if polarization is neglected it drops to 0.028. An experiment with 2000 events would measure this parameter to better than .001. Likewise,
at 14.5 GeV a 2000 event experiment easily distinguishes the
two distributions as the second moment is 0.051, while it drops
to 0.044 when the polarization is neglected. The 2000 event experi-
ment would have an uncertainty of slightly more than 0.001.

In conclusion, we have stressed that the decay of a heavy
lepton into a spin one particle and a neutrino results in a polariza-
tion of the meson if the decay proceeds via the conventional V - A
current. Furthermore, the laboratory energy distribution of pions
carries through the polarization information even though the \( \tau \)
leptons themselves are not polarized. This experimental verifica-
tion of the nature of the decay current does not require knowledge
of the \( \tau \) laboratory direction.

We acknowledge useful discussions with our colleagues at SLAC.

6. The non-vanishing elements of the rho density matrix are

\[ \rho_{00} = C \frac{M^2}{\tau^2} \rho \left( 1 - \eta \frac{\hat{s} \cdot \hat{k}}{\tau} \right) \]

\[ \rho_{\alpha \lambda} = C \frac{\sqrt{2} M}{\tau} \frac{(1 + \lambda \eta)}{2} \eta \frac{\hat{s} \times \hat{k}}{\tau} \frac{\hat{r}}{||\hat{k}||} \]

\[ \rho_{\alpha \lambda} = C \left( 1 + \lambda \eta \right) \left( 1 + \eta \frac{\hat{s} \cdot \hat{k}}{\tau} \right) \frac{\hat{r}}{||\hat{k}||} \]

where C is a normalization function, and \( \rho \) is the polarization of the \( \tau \). If the direction of \( \tau \) spin and the neutrino were known, as foreseen in the future linear colliders, the angular distributions of pions in the rho rest-frame would show the azimuthal anisotropy expected from the finite off-diagonal density matrix elements.
