Abstract

The structural and electrochemical properties of RuPt thin-film electrodes fabricated by RF magnetron sputtering have been investigated. Grazing incidence X-ray diffraction data show a transition from a face-centred-cubic (fcc) to hexagonal-cubicpacked (hcp) structure as Ru percentage increases. The transition occurs gradually between 32-58% Ru, which is significantly different from the bulk RuPt phase diagram. The catalytic activity of the thin-film electrodes for methanol oxidation shows a broad peak near 40-60% Ru, consistent with previous reports. The relationship between catalytic activity and film structure is discussed and contrasted with previous investigations.

1. Introduction

Due to various merits such as high energy density, low operating temperature, easy handling, simple processing and the possibility of applications to micro-fuel cells, direct methanol fuel cells (DMFCs) are currently undergoing rapid development [1-9]. The excellent catalytic activity of platinum-based alloy nanoparticles for methanol oxidation makes this metal electrocatalyst ideal for use as an anode in DMFCs. However, it is well known that CO, a by-product in methanol electrooxidation readily poisons pure platinum at low temperatures. Accordingly, much effort has been reported to design and synthesize Pt-based alloy catalysts by alloying platinum with a second element to enhance its catalytic activity for methanol electrooxidation by eliminating the CO poisoning effect [10-15]. Watanabe *et al.* have extensively studied Pt-based alloy catalysts designed according to the bifunctional mechanism in DMFCs [16]. Here oxygen species adsorbed on the alloying element, such as ruthenium, regenerate the CO poisoned platinum by oxidizing the CO to CO_2 [16, 17].

The catalytic activity of RuPt nanoparticles and RuPt alloys is sensitive to catalyst composition and structure. With increasing Ru, the structure of PtRu changes from facecentered cubic (fcc) to hexagonal close packed (hcp) [18-20]. Other researches have reported that the composition and structure of supported PtRu nanoparticles affects the catalytic activity [18, 19, 21-26]. Park *et al.* observed that 40-60 at % Ru in RuPt alloy catalysts is optimum for achieving excellent catalytic activity in methanol oxidation [27]. However, there has been little systematic work on the relationship between the structural and electrochemical properties of RuPt thin-film electrocatalysts with a range of structure and composition. In this paper, PtRu thin-film electrodes with varying composition were prepared for methanol electrooxidation. Characterization of the thin films was carried out using grazing incidence X-ray diffraction (GIXD) and electrochemical measurements. We relate between structural and electrochemical properties in PtRu thin-film electrodes.

Experimental Section

RuPt thin-film electrodes were grown using a RF magnetron sputtering system with different conditions. P-type (100) silicon and Indium tin oxide (ITO, Samsung Corning Co, Ltd) were used as substrates to characterize structural and electrochemical property, respectively. Ruthenium and platinum were used as target materials. In order to fabricate the RuPt thin-film electrodes, co-sputtering was used with different RF powers [27]. Co-sputtering was performed under the inert Ar gas at a flow rate of 40 SCCM at room temperature for 20 minutes, which produced films about 130 Å thick. In order to fabricate RuPt thin-film electrodes with varying composition, guns with metal targets in the RF magnetron sputtering system were controlled as a function of RF power. With increasing the RF power of the Ru target gun at fixed RF power of platinum gun, the Ru concentration was varied from 0 to 85%. A pure Ru film was also produced.

Grazing Incidence X-ray Diffraction (GIXD) analysis was carried out using beam line 7-2 at the Stanford Synchrotron Radiation Laboratory. The X-ray energy was either 9 or 10 keV (wavelength (λ) of about 1.38 and 1.24 Angstrom, respectively). In the diffraction measurements, the sample was held to a Huber four-circle diffractometer by a vacuum chuck and was surrounded by a Helium atmosphere to reduce unnecessary scattering of x-rays from the air near the sample. An ion chamber, placed after the beam defining slits, was used for incident flux normalization. The incidence angle was approximately 0.6 degrees, just about the critical angle for total reflection for Pt-Ru alloys. After grazing the sample, the diffracted beams passed through 1 milliradian Soller slits, used to define the scattering angle, before reaching the detector.

Electrochemical measurements were made using a three-electrode cell at 25 °C. The deposited RuPt thin-film electrodes, Pt gauze and an Ag/AgCl (in saturated KCl) were used as the working, counter and reference electrodes, respectively. All potentials are reported vs. Ag/AgCl (in saturated KCl) reference electrode. All chemicals were of analytical grade. All solutions for electrochemical measurements were stirred constantly and purged with nitrogen gas. Electrochemical experiments were performed with AUTOLAB (Eco Chemie). In order to identify electrochemical properties of the RuPt thin-film electrodes, cyclic voltammetry (CV) was performed in the potential range between $-0.3 \sim 0.8$ V versus Ag/AgCl in 0.5M H₂SO₄ solution. The electrocatalytic activity for methanol electrooxidation was measured in 2.0 M CH₃OH in 0.5 M H₂SO₄.

Results

Structural properties of RuPt thin-film electrodes by GIXD analysis

Before describing our data, it is useful to briefly review the bulk phase diagram for Ru-Pt alloys [20, 28, 29]. For Ru atomic fractions up to 62%, Pt and Ru form a solid solution with a face-centered cubic (fcc) structure, while the lattice parameter decreases from 3.925 (pure Pt) to 3.85 Å at 62% Ru. Above 80% of Ru, a solid solution with an hexagonal close packed (hcp) structure forms. Between these compositions, the alloys form a two-phase region of mixed fcc and hcp.

Figure 1 shows the GIXD data for well-defined RuPt thin-film electrodes as a function of increasing Ru from bottom to top. These data are plotted as a function of the scattering vector $Q = (4\pi/\lambda) \sin \theta$, where θ is half the scattering angle. Some of the diffraction peaks for both fcc and hcp alloys are noted. This figure reveals several important points. First, as the Ru fraction increases, the crystal structure of the film changes from fcc to hcp. Below about 40% Ru, the films are fcc, while above about 65% Ru, the films adopt an hcp structure. Between these compositions, the films appear to be mixed fcc and hcp. Second, the diffraction peaks shift to higher Q with increasing Ru, which is due to a decrease in the lattice parameters. Last, the peaks are rather broad, which implies a small grain size. We have also measured the crystallographic texture in these films and find that for the fcc and mixed phase films there is a weak fcc(111)/hcp(002) texture, while for the hcp films there is a somewhat stronger hcp(002) texture (which is evident by the weak hcp(002) peaks in Fig. 1).

From the data in Fig. 1, we can extract the approximate percentage of fcc and hcp alloys present in the thin films. Figure 2(a) shows the normalized, integrated intensity of the hcp(100), fcc(111)/hcp(002) (which are indistinguishable), hcp (101) and fcc(200) peaks as a function of Ru concentration. The intensities are normalized by dividing the peak intensities by the sum of the intensities of these four peaks; this removes differences in the raw data due to different X-ray energies and slightly different incidence angles. As can be seen, the trends in the intensities of the fcc peaks and the hcp peaks are mutually consistent, which confirms the validity of this approach for estimating the phase fractions. We can quantify this further by taking into account the atomic form factors, multiplicities, and Lorenz-Polarization factor and calculating the fcc fraction from the hcp(101) and fcc(200) peaks, which are strong and clearly distinct

(i.e., do not overlap other peaks). This is shown in Fig. 2(b). As is apparent the hcp phase begins to form near 40% Ru and is complete just above 60% Ru. This is different from the expectations of the bulk phase diagram, and this is highlighted in Fig. 3, which shows both the bulk [20, 28, 29] and our "thin-film phase diagram". The co-sputtering method shifts the phase diagram significantly, and the phase transition boundary changes markedly from to 62-80% Ru in bulk to approximately 32-58% Ru in the films. This will be contrasted to the electrochemical behaviour of the alloys below.

Before turning to the electrochemistry, it is interesting to examine the lattice parameters and these are shown in Fig. 4 as a function of Ru fraction. The solid symbols are the lattice parameters calculated from the GIXD data (Fig. 1), while the open symbols are calculated from the specular (usual $\theta/2\theta$ geometry) data (not shown). The solid lines are values for the bulk fcc and hcp phases [20], while the dashed lines are guides to the data. The error bars are larger in the mixed phase region, because many of the fcc and hcp peaks overlap. In both hcp and fcc phases, the lattice parameters decrease as the percentage Ru increases, with the smaller Ru atoms substituting for Pt. For the hcp phase (Fig. 4(a) and (b)), a and c are not too different from the bulk values. However, for the fcc phase (Fig. 4(c)), the thin-film data show a different trend from the bulk with a more pronounced dependence on Ru fraction. The film two-phase region (32% - 58%) manifests itself as a plateau in the lattice parameters. Note that since the thin-film and bulk lattice parameters are different, one cannot use empirically determined lattice parameters to infer film composition.

Electrochemical properties of RuPt thin-film electrodes

The GIXD data show the dependence of the structural properties on film composition

and the difference between bulk RuPt alloy and thin-film phase diagrams. Since RuPt nanoparticles with different compositions have distinct electrochemical properties, especially for methanol electrooxidation, the electrochemical properties of our RuPt thin-films will also depend on composition, which, in turn, is dependent on the RF power of Pt and Ru sputtering targets. This is the case as shown in Fig. 5, which plots the cyclic voltammetry (CV) for the thin-film electrodes with several compositions. Compared with the solid line (28.8% Ru), the dotted line (46.2% Ru) shows a larger double layer thickness in the potential range of 0.0 - 0.4V and a lower oxygen reduction potential (shown by the arrow in Fig 5). For the 67.0% Ru alloy (dashed line in Fig. 5), the double layer is significantly thicker and the oxygen reduction potential is much lower. The thickness of the double layer region increases with increasing Ru composition because of the increased hydrophilicity of Ru. The oxygen reduction potential decreases due to the slow kinetics of Ru in RuPt thin-film electrode for oxygen reduction.

Fig. 6 shows a plot of the current density for methanol electro-oxidation with respect to applied potential for RuPt thin-film electrodes containing 28.8%, 46.2% and 67.0% Ru. As is apparent, the thin film with 46.2% Ru has the highest catalytic activity, consistent with studies on similar systems [27]. Recall that this film has mixed fcc and hcp structure. Fig. 7 shows the Ru dependence of the methanol electro-oxidation current density of RuPt thin-film electrodes at 0.4 V. As is apparent, there is a broad maximum in the catalytic activity in the range 40 - 60 at % Ru with the highest catalytic activity in the thin film containing 46.2% Ru. Furthermore, the catalytic activity of Ru-rich region was relatively higher than that of Pt rich-region.

Discussion

It has been reported that for supported and unsupported nanoparticle RuPt catalysts 40-60% Ru gives the optimum catalytic activity for methanol oxidation [24-27, 30, 31]. Similarly, in bulk RuPt alloys the best catalytic activity is found for \approx 50% Ru in the bulk alloy [32, 33]. In these articles, the RuPt alloy is in the fcc phase. Indeed, it has been reported that the fcc phase is stabilized in RuPt nanoparticles beyond the bulk stability limit (62% Ru). For example, for 2.5 nm RuPt nanoparticles prepared on carbon supports by the reduction of molecular precursors, mostly fcc nanoparticles are obtained for up to 80 at% Ru [21]. Similarly, for 2.5-4.5 nm nanoparticles prepared by water-in-oil microemulsions, an fcc alloy is found up to at least 65 at% Ru [22].

Our sputtered films, however, seem to be different from these nanoparticles in that the fcc phase is less stable than for bulk and the hcp phase is formed at a low Ru concentration (see Fig. 3). Despite this structural difference, we also find, consistent with supported and unsupported RuPt catalysts, that the maximum in the catalytic activity for methanol electro-oxidation lies in the range 40-60% Ru (see Fig. 7). These results suggest that the presence of hcp RuPt does not affect methanol oxidation in contrast to previous assumptions [23]. Our findings are consistent with other work on sputtered WO_x-RuPt nanostructures in that a 40-60% Ru alloy gives the best catalytic activity but is mixed fcc/hcp phase [34].

According to the bifunctional mechanism [16], oxygen containing species adsorbed on Ru surface atoms react with CO-poisoned platinum sites yielding CO_2 and regenerating an active Pt site. In modeling studies of this process [35, 36], the alloys are assumed to be fcc. Since the arrangement of surface atoms depends on the bulk structure and crystal face exposed, our results show this assumption is necessarily not valid for all electrocatalysts. This result can be important with respect to mechanism of Ru enhancement.

Summary and Conclusions

To understand structural and electrochemical properties of PtRu for methanol electrooxidation, we prepared sputtered PtRu thin-film electrodes with different composition and structure. From the GIXD data, we observed that the RuPt thin-film electrodes evolved from fcc through mixed fcc/hcp to hcp structures as the Ru concentration increased. The phase diagram for sputtered RuPt thin-film electrodes was significantly different from the bulk phase diagram, with the fcc-to-hcp transition in the films occurring at 32-58% Ru, while the bulk transition is at 62-80% Ru. In the electrochemical measurements, the thin-film electrodes showed a broad region of maximum catalytic activity for methonal oxidation at 40-60% Ru. Significantly, the RuPt electrodes with mixed phase showed excellent catalytic activity.

Our results show that the presence of hcp RuPt does not adversely affect the catalytic activity of the alloys for methonal oxidation and that the assumption of an fcc structure for RuPt alloys is not necessarily valid for low Ru concentrations. They further show that the bulk phase diagram is not good guide to thin film structure for these materials. Finally, the existence of strain shows that one cannot use the diffraction peak positions to infer Ru concentration in the alloys.
