Abstract

We propose and analyze a novel regenerative amplifier free electron laser (FEL) to produce fully coherent x-ray pulses. The method makes use of narrow-bandwidth Bragg crystals to form an x-ray feedback loop around a relatively short undulator. Self-amplified spontaneous emission (SASE) from the leading electron bunch in a bunch train is spectrally filtered by the Bragg reflectors and is brought back to the beginning of the undulator to interact repeatedly with subsequent bunches in the bunch train. The FEL interaction with these short bunches not only amplifies the radiation intensity but also broadens its spectrum, allowing for effective transmission of the x-rays outside the crystal bandwidth. The spectral brightness of these x-ray pulses is about two to three orders of magnitude higher than that from a single-pass SASE FEL.

Submitted to Phys. Rev. Lett.

An x-ray free electron laser (FEL) based on self-amplified spontaneous emission (SASE) is an important first step towards a hard x-ray laser and is expected to revolutionize the ultrafast x-ray science (see, e.g., Refs. [1, 2]). Despite its full transverse coherence, a SASE x-ray FEL starts up from electron shot noise and is a chaotic light temporally. Two schemes have been proposed to improve the temporal coherence of a SASE FEL in a single pass configuration. A high-gain harmonic generation (HGHG) FEL uses available seed lasers at ultraviolet wavelengths and reaches for shorter wavelengths through cascaded harmonic generation [3]. In this process, the ratio of electron shot noise to the laser signal is amplified by at least the square of the harmonic order and may limit its final wavelength reach to the soft x-ray region [4]. Another approach uses a two-stage SASE FEL and a monochromator between the stages [5]. The SASE FEL from the first undulator is spectrally filtered by a monochromator and is then amplified to saturation in the second undulator. This approach requires an undulator system almost twice as long as a single-stage SASE FEL.

Another seeding scheme, a regenerative amplifier FEL (RAFEL), has been demonstrated in the infrared wavelength region [6] and discussed in the ultraviolet wavelength region [7]. It consists of a small optical feedback and a high-gain FEL undulator. In the hard x-ray region, perfect crystals may be used in the Bragg reflection geometry for x-ray feedback [8, 9] and have been demonstrated experimentally for x-ray photon storage (see, e.g., Ref. [10, 11]). In this paper, we propose and analyze a novel x-ray RAFEL using narrow-bandwidth, high-reflectivity Bragg mirrors. The basic schematic is shown in Fig. 1. Three Bragg crystals are used to form a ring x-ray cavity around a relatively short undulator. Alternative backscattering geometry with a pair of crystals may also be used. SASE radiation from the leading electron bunch in a bunch train is spectrally filtered by the Bragg reflectors and is brought back to the beginning of the undulator to interact with the second bunch. This process continues bunch to bunch, yielding an exponentially growing laser field in the x-ray cavity. The FEL interaction with these short bunches not only amplifies the radiation intensity but also broadens its spectrum. The downstream crystal transmits the part of the radiation spectrum outside its bandwidth and feeds back the filtered radiation to continue the amplification process. Compared to a SASE x-ray FEL that typically requires more than 100 m of undulator distance, this approach uses a significantly shorter undulator but a small number of electron bunches to generate multi-GW x-ray pulses with excellent temporal coherence. The resulting spectral brightness of these x-ray pulses can be another two to three orders of
FIG. 1: (Color) Schematic of an x-ray RAFEL using three Bragg crystals.

magnitude higher than the SASE FEL.

We first consider a one-dimensional (1-D) model of the narrow-bandwidth RAFEL to describe its main characteristics such as the temporal profile, the round-trip power gain and the maximum extraction efficiency. At the beginning of the nth undulator pass, the radiation field is represented by $E_n(t)$, where t is the arrival time relative to the longitudinal center of the electron bunch. The radiation field at the exit of the undulator is

$$E_n^a(t) \approx E_n(t)g(t) + \delta E_n(t) \,, \tag{1}$$

where $\delta E_n(t)$ is the SASE signal of the nth electron bunch. When the radiation slippage length is much smaller than the electron bunch length, we can assume the electric field gain factor $g(t)$ is a function of the local beam current which can be approximated by

$$g(t) \approx g_0 \exp\left(-\frac{t^2}{2\sigma_\tau^2}\right) \,, \tag{2}$$

where σ_τ is the rms pulse duration of a Gaussian bunch current. The more precise gain dependence on the current is used in numerical simulations shown below.

The amplified signal is then spectrally filtered by the Bragg mirrors and is fed back to the entrance of the undulator in the $(n+1)^{th}$ pass, i.e.,

$$E_{n+1}(t) = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} e^{-i\omega t} \int_{-\infty}^{\infty} dt' E_n^a(t') e^{i\omega t'} f(\omega - \omega_r) \,, \tag{3}$$

where $f(u) = r \exp\left(-u^2/4\sigma_m^2\right)$ is a Gaussian spectral filter function with the rms intensity bandwidth σ_m, and ω_r is the central frequency of the filter with the power reflectivity $|r|^2 \leq 1$. For a high-gain amplifier after a few passes, the seed signal dominates over the SASE, so that we can neglect the second term on the right side of Eq. (1). Integrating Eq. (3) over

the frequency yields

$$E_{n+1}(t) = \int_{-\infty}^{\infty} dt' \frac{r\sigma_m}{\sqrt{\pi}} e^{-i\omega_r(t-t')} e^{-\sigma_m^2(t-t')^2} g(t') E_n(t') \,. \tag{4}$$

Since there is no initial seed signal, $E_1(t) = 0$, and

$$E_2(t) = \int_{-\infty}^{\infty} dt' \frac{r\sigma_m}{\sqrt{\pi}} e^{-i\omega_r(t-t')} e^{-\sigma_m^2(t-t')^2} \delta E_1(t') \tag{5}$$

is the spectrally filtered SASE from the first pass that seeds the second pass.

For $n \gg 1$, we look for an exponentially growing solution

$$E_n(t) = \Lambda^n A(t) e^{-i\omega_r t} \,. \tag{6}$$

Eq. (4) is then transformed to an integral equation:

$$\Lambda A(t) = \int_{-\infty}^{\infty} dt' K(t, t') A(t') \,, \tag{7}$$

with the kernel

$$K(t, t') = \frac{r\sigma_m}{\sqrt{\pi}} e^{-\sigma_m^2(t-t')^2} g(t') \,. \tag{8}$$

Since both r and $g(t')$ may be complex, $K(t, t')$ is in general not a hermitian kernel.

We expect that a Gaussian fundamental mode will have the largest gain $|\Lambda_0|$, i.e.,

$$A_0(t) = \exp\left(-\frac{t^2}{4\sigma_{x0}^2}\right) \,. \tag{9}$$

Here σ_{x0} is the rms pulse duration of the returning filtered radiation. Inserting Eq. (9) into Eq. (7), we obtain

$$\Lambda_0 \exp\left(-\frac{t^2}{4\sigma_{x0}^2}\right) = g_0 r \frac{2\sigma_m \sigma_{xa}}{\sqrt{1 + 4\sigma_m^2 \sigma_{xa}^2}} \exp\left(-\frac{\sigma_m^2 t^2}{1 + 4\sigma_m^2 \sigma_{xa}^2}\right) \,, \tag{10}$$

where $\sigma_{xa} = \sigma_{x0}\sigma_\tau / \sqrt{2\sigma_{x0}^2 + \sigma_\tau^2}$ is the rms x-ray pulse duration at the undulator end (see Eq. (14)). The self-consistent solution of Eq. (10) is

$$\sigma_{x0}^2 = \frac{1 + 4\sigma_m^2 \sigma_{xa}^2}{4\sigma_m^2} = \frac{\sqrt{1 + 8\sigma_m^2 \sigma_\tau^2} + 1}{8\sigma_m^2} \,,$$

$$\sigma_{xa}^2 = \frac{\sqrt{1 + 8\sigma_m^2 \sigma_\tau^2} - 1}{8\sigma_m^2} \,, \tag{11}$$

$$\Lambda_0 = g_0 r \frac{2\sigma_m \sigma_{xa}}{\sqrt{1 + 4\sigma_m^2 \sigma_{xa}^2}} \,.$$

Thus, the round-trip power gain is

$$G_{\text{eff}} \equiv |\Lambda_0|^2 = G_0 R \frac{4\sigma_m^2 \sigma_{xa}^2}{1 + 4\sigma_m^2 \sigma_{xa}^2}$$
$$= G_0 R \frac{\sqrt{1 + 8\sigma_m^2 \sigma_\tau^2} - 1}{\sqrt{1 + 8\sigma_m^2 \sigma_\tau^2} + 1} . \tag{12}$$

where $G_0 = |g_0|^2$ is the peak FEL gain, and $R = |r|^2$ is the peak reflectivity of the feedback system. Regenerative amplification requires that $G_{\text{eff}} > 1$. Note that G_{eff} depends on the time-bandwidth product $\sigma_m \sigma_\tau$, but not on σ_m or σ_τ separately.

The filtered radiation power at the undulator entrance for $n \gg 1$ is then

$$P_n(t) = |E_n|^2 = P_0 G_{\text{eff}}^n \exp\left(-\frac{t^2}{2\sigma_{x0}^2}\right) , \tag{13}$$

where P_0 is the effective noise power within the narrow bandwidth that starts the process. The amplified radiation at the end of the nth undulator pass is

$$P_n^a(t) = |E_n^a|^2 = P_0 G_0 G_{\text{eff}}^n \exp\left(-\frac{t^2}{2\sigma_{xa}^2}\right) , \tag{14}$$

with σ_{xa} given by Eq. (11). If we neglect any absorption in the crystal, the part of the radiation energy (with frequency content mainly outside the feedback bandwidth) may be transmitted with the maximum efficiency

$$\eta = \frac{\int P_n^a(t)dt - \int P_{n+1}(t)dt}{\int P_n^a(t)dt} = 1 - R\sqrt{\frac{4\sigma_m^2 \sigma_{xa}^2}{1 + 4\sigma_m^2 \sigma_{xa}^2}} . \tag{15}$$

In view of Eq. (12), the maximum extraction efficiency is also a function of the time-bandwidth product $\sigma_m \sigma_\tau$.

As a numerical example, we discuss how the proposed RAFEL might be implemented in the Linac Coherent Light Source (LCLS) [1]. The x-ray wavelength is chosen to be about 1.55 Å since diamond (400) crystals may be used at a Bragg angle $\theta_B = 60°$. The diamond (115) reflection plane may be as well chosen at 1.2 Å for the same Bragg angle. Three such crystals are necessary to form an x-ray cavity as shown in Fig. 1. The reflectivity curve of a 100-μm-thick diamond (400) crystal for the 8-keV, π-polarized radiation is shown in Fig. 2 as computed by XOP [12]. The x-ray reflectivity $R \approx (97\%)^3 \approx 91\%$ within the Darwin width $\Delta\theta_D \approx 7$ μrad, corresponding to the flattop region of Fig. 2 with $\Delta\omega_m/\omega_r = \Delta\theta_D/\tan\theta_B \approx 4 \times 10^{-6}$. The expected rms angular divergence of the FEL radiation is about 0.5 μrad, which is well within the Darwin width but washes out the interference fringes shown in
FIG. 2: X-ray reflectivity of a 100-μm-thick diamond (400) crystal for 8-keV, π-polarized radiation. Fig. 2. The crystals may be bent slightly to provide the necessary focusing of the filtered radiation at the undulator entrance.

In order to accelerate a long bunch train in the SLAC linac, we use the entire rf macropulse available without the rf pulse compression (SLED). The maximum LCLS linac energy, without the SLED, is about 10 GeV. Table I lists the beam and undulator parameters that are typical for x-ray FELs such as the LCLS, except that the length of the undulator is only 20 m instead of more than 100 m planned for the LCLS. We perform the three-dimensional (3-D) GENESIS [13] FEL simulation that shows the maximum power gain $G_0 \approx 39$ after the 20-m undulator, with the fwhm relative gain bandwidth about 2×10^{-3} (see Fig. 3). The LCLS accelerator and bunch compressor systems are expected to generate a bunch current profile which is more flattop than Gaussian, with a flattop duration $T = 100$ fs [1]. If we take $\sigma_\tau \approx T/2.35$ and $\sigma_m \approx \Delta\omega_m/2.35$ in Eq. (12), we obtain the round-trip gain $G_{\text{eff}} \approx 16$ under these parameters.

We have developed a 1-D FEL code that simulates the regenerative amplification process. The electron rms energy spread is increased in the 1-D code to 3.8×10^{-4} so that the 1-D FEL gain matches the 3-D FEL gain $G_0 = 39$ determined by parameters in Table I. The simulation using a flattop current profile and a nearly flattop crystal reflectivity curve shows that the round-trip gain $G_{\text{eff}} \approx 14$ in the exponential growth stage and that the RAFEL reaches saturation within 10 x-ray passes. For a total x-ray cavity length of 75 m (25 m for each of three cavity arms in Fig. 1), the duration of the 10-bunch train is about 2.25 μs, well within the 3.5-μs uncompressed rf pulse length even after taking into account the structure

TABLE I: Parameters for an x-ray RAFEL.

Parameter	Symbol	Value
electron energy	γmc^2	9.9 GeV
number of bunches		10 to 11
bunch spacing		~ 0.25 μs
bunch charge	Q	~ 300 pC
bunch peak current	I_{pk}	3 kA
fwhm bunch duration (flattop)	T	100 fs
rms energy spread at undulator	σ_E/E	1×10^{-4}
transverse norm. emittance	$\gamma\varepsilon_{x,y}$	1 μm
undulator mean beta function	$\beta_{x,y}$	18 m
undulator period	λ_u	0.03 m
undulator parameter	K	2.4
FEL wavelength	λ_r	1.55 Å
photon energy	$\hbar\omega_r$	8 keV
FEL parameter	ρ	5×10^{-4}
undulator length	L_u	20 m
maximum FEL gain per pass	G_0	39
3-crystal bandwidth	$(\Delta\omega_m/\omega_r)$	4×10^{-6}
3-crystal reflectivity	R	91%

filling time ($\sim$ 0.8 μs). The beam loading is estimated to be small for less than 2 mA average current within the bunch train. To stay within the FEL gain bandwidth as shown in Fig. 3, the relative energy variation within the bunch train should be less than $\pm 0.05\%$. A bunch-to-bunch time jitter of about ± 100 fs would require a 11-bunch train of 2.5 μs in order for the FEL to reach saturation.

Figure 4 shows that the radiation energy at the undulator end is mainly the broadband SASE radiation in the first three passes or so and is then dominated by the narrow bandwidth filtered signal up to the FEL saturation. Figures 5 shows the temporal profile of the reflected and transmitted FEL power for a 100-μm-thick diamond crystal with about 82% transmission outside the crystal bandwidth around 8 keV. The broadband SASE radi-

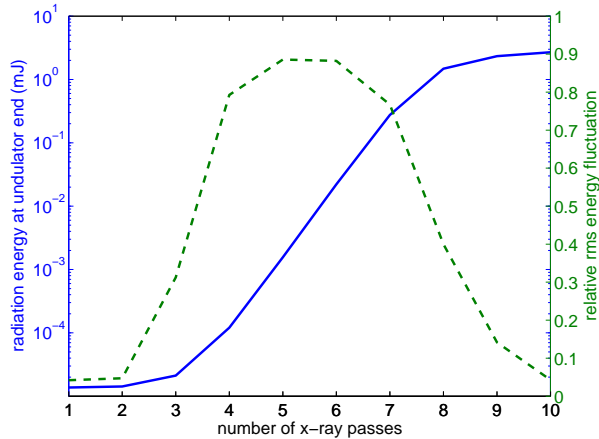

FIG. 4: (Color) Average radiated energy (blue solid line) and relative rms energy fluctuation (green dashed line) at the undulator end.

ation transmitted through the end crystal (the noisy part of the blue solid curve in Fig. 5) can be separated from the narrow-bandwidth signal by another monochromator following the transmission as demonstrated in Fig 6. The total x-ray energy dose absorbed by the undulator-end crystal (FEL plus spontaneous radiation) is estimated to be two orders of magnitude smaller than the melting dose level for diamond. Finally, Fig. 4 also shows that the shot-to-shot radiation energy fluctuates up 90% in the exponential growth stage but quickly reduces to about 5% at the end of the 10th pass. Although a monochromator may also be used in a saturated SASE FEL to select a single longitudinal mode, the radiation power will be reduced by the ratio of the SASE bandwidth to the monochromator bandwidth,
FIG. 5: (Color) Temporal profile of the reflected (green dashed line) and transmitted (blue solid line) FEL power at the end of 10th pass.

FIG. 6: Temporal profile of the final transmitted FEL power after passing a monochromator with a fwhm bandwidth $2\Delta\omega_m/\omega_r = 8 \times 10^{-6}$ to filter out the SASE radiation.

and the filtered radiation energy still fluctuates 100%.

While we consider a ring x-ray cavity with 60° Bragg reflection for illustration, the RAFEL scheme and its analysis presented in the paper is equally applicable to a backscattered x-ray cavity with 90° Bragg reflection. The round-trip time of such a cavity is only two thirds of the ring cavity shown in Fig. 1, allowing for 50% more electron bunches in a bunch train of the same duration to participate in the RAFEL process. The reflectivity at exactly 90° Bragg reflection for cubic crystals such as diamond may be complicated by multiple-wave diffraction and has not been studied here. Crystals with lower structure symmetry such as sapphire may provide the necessary high reflectivity in backscattering as demonstrated in

9

Ref. [11].

In summary, we have described a narrow-bandwidth regenerative amplifier FEL (RAFEL) at the hard x-ray wavelength region using Bragg crystals that produces nearly transform limited x-ray pulses in both transverse and longitudinal dimensions. Compared to a SASE x-ray source that possesses a typical bandwidth on the order of 10^{-3}, the bandwidth of an x-ray RAFEL can be more than two orders of magnitude smaller, resulting in a factor of a few hundred improvement in spectral brightness of the radiation source. The use of multiple bunches in a bunch train for regenerative amplification allows for a relatively short undulator system and may be adapted in the LCLS using the SLAC s-band linac. Since superconducting rf structures can support a much longer bunch train in an rf macropulse, an x-ray RAFEL based on a superconducting linac may require a much lower single pass gain and hence relax some of beam and jitter requirements provided that the additional radiation damage to the x-ray optics is tolerable. Therefore, the method described in this paper is a promising approach to achieve a fully coherent x-ray laser.
