Incremental Cost of Encoding Data in a Tape-Based Information Storage and Retrieval System
or
It's Dirt Cheap to Scramble Your Data!

Up to this point, no published results have appeared dealing with the cost of encoding (scrambling) information in an information storage and retrieval system. Opponents of more stringent access controls in computer systems have cited the high cost of adding additional software control functions to the already overburdened operating systems, but to this author's knowledge no hard timing data has yet appeared.

In a quest for some ballpark figures on the costs of encoding data, (and conversely the costs of decoding data), an experiment was run on the IBM 360/67 computer system at the Campus Facility of Stanford University Computation Center. A tape containing 1,050 80-character card images in clear (unscrambled) format was generated and the 80-character records were sequentially read in, scrambled, and the (encoded) card images written out on a new output tape. The appendix contains the listing of the FORTRAN program used to do this job, and also the printout of the timing results.

As can be seen by an examination of the printout, the time used to scramble 1,050 cards using the simple encoding technique shown in the program listing, was 7.5612 seconds. (Actually this is the time used to scramble 1,049 cards, since writing of the first output record required a one-time opening of the data set by the operating system. Since we were trying to get an estimate of the time required to encode a large number of records, this "open time" was disregarded. It would certainly be negligible for any

large-scale data base.) This time, 7.5612 seconds, is the total wall-clock time used from the time the first clear record was read in until the time the last encoded record was written out onto the output tape. All waits for input/output, etc., are included in this time. Again, the time does not represent central processor cycles. It is wall-clock time on a system where this was the only job running in addition to the operating system. (In other words, this job used the entire 600K byte partition on the 360/67.) The experiment was carried out in this manner in order to get a high estimate of the incremental cost involved in scrambling a large number of cards. In a multi-programming system the actual time used in encoding could be overlapped with tasks from other jobs and therefore would not nearly be so costly.

In this worst case we see that 1,049 cards were scrambled in 7.5612 seconds. We can put it another way; the incremental cost of encoding one card image on this system is .007 seconds. Uder the existing rate structure at the Stanford Computation Center, it then costs 0.08 cents to encode each card image. Therefore, encoding one card image (80 bytes of information) for each of the 20,000,000 residents of the State of California would cost only $16,000.

Conclusion

The incremental cost of scrambling information in a large computer data base seems infinitesimal.

Appendix. Printout from Experiment, Including FORTRAN Code and Results
